Space (Length) Constant, Lambda, in Neuronal Signaling

William R. Holmes
Department of Biological Sciences, Ohio
University, Athens, OH, USA

Definition

The space (length) constant λ with $\lambda = (R_m d / (4R_a))^{1/2}$ is a measure of steady-state voltage decay with distance in a cell. Quantitatively λ is the distance over which the steady-state voltage decays to $1/e$ or 37% of its value at the origin in a semi-infinite cable.

Detailed Description

As given in the definition above, the space constant λ with $\lambda = (R_m d / (4R_a))^{1/2}$ is a measure of steady-state voltage decay in a cell. Quantitatively λ is the distance (usually expressed in cm or μm) over which the steady-state voltage decays to $1/e$ or 37% of its value at the origin in a semi-infinite cable. This can be seen by solving the steady-state cable equation (Rall 1977)

$$\lambda^2 d^2 V / dx^2 - V = 0$$

with boundary conditions of voltage clamp to V_0 at the origin and voltage bounded at $x = \infty$ to get

$$V(x) = V_0 \exp(-x/\lambda)$$

The above equation is useful to describe voltage displacements from rest. A more general solution for voltage decay with distance that includes resting potential explicitly is

$$V(x) = V_{\text{rest}} - (V_{\text{rest}} - V_0) \exp(-x/\lambda)$$

where now V_0 is actual voltage instead of a difference from rest.

The importance of λ is that it determines how spatially separated inputs are integrated (spatial summation). If λ is small, then spatially separated inputs are unlikely to sum because voltage will decay significantly over the distance between the inputs, but if λ is large, inputs will not decay as much with distance allowing summation to occur. Given the formula for λ , spatial summation is more likely to occur when diameter or membrane resistivity is large or axial resistivity is small.

One must be careful not to equate quantitatively the steady-state voltage decrement with distance for the semi-infinite cylinder with voltage decay in finite cylinders. For finite cylinders steady-state voltage decay with distance will depend strongly on both the boundary conditions and the length of the cylinders (see entry ► “Cable Equation”), and for transient inputs voltage decay with distance will be very different. Conductance changes associated with transient inputs may make λ variable in time; depending on the level of background synaptic activity, λ may be large at one moment and small at another causing effective spatial integration to vary widely.

The definition of λ given above is for the special case where extracellular voltage is assumed to be isopotential. In the derivation of the cable equation, a generalized λ is defined as

$$\lambda = \sqrt{\frac{r_m}{r_i + r_e}}$$

where r_m is membrane resistance of a unit length of membrane in Ωcm and r_i and r_e are the intracellular and extracellular resistances per unit length in Ω/cm . In single cell models, it is usually appropriate to neglect r_e unless ephaptic interactions are a concern. If we neglect r_e then

$$\lambda = \sqrt{\frac{r_m}{r_i}} \text{ or in terms of specific resistivities}$$

$$\lambda = \sqrt{\frac{R_m d}{4R_a}}$$

Setting r_c to 0 in the above expression for λ leads to another insight when the equation is expressed as $\lambda r_i = r_m/\lambda$. What this equation says is that λ corresponds to the length of the core conductor for which the core resistance (λr_i) equals the resistance (r_m/λ) across the membrane.

Spatial Spectral Analysis

Armin Fuchs

Center for Complex Systems and Brain Sciences,
Florida Atlantic University, Boca Raton, USA

Definition

Spatial spectral methods are extensions of the well-known Fourier transform in time into the spatial domain. Whereas the basis functions for the Fourier transform are sine and cosine or complex exponentials, the bases used in space often reflect a symmetry of the problem. Common basis sets are plane waves (Cartesian space), Bessel

functions (circular and cylindrical symmetry), and spherical harmonics (sphere). Moreover, basis vectors can be derived from the dataset under consideration that are optimal with respect to certain criteria like mean squared error.

Detailed Description

Spectral methods are best known from the Fourier transform that decomposes a time series into its frequency components. Spectral methods in space are applied to datasets that are recorded at different locations in space like EEG (electroencephalography is recorded with up to several hundred electrodes attached to different locations on the scalp surface), MEG (magnetoencephalography measures the magnetic field created by electric currents inside the brain at the locations of sensors surrounding the head), or even fMRI (functional magnetic resonance imaging, where brain activity is measured at locations inside a 3-dimensional volume).

In general, a spatial pattern that evolves in time is decomposed into a set of functions that depend only on space and corresponding time series representing their amplitudes. To be specific, one can think of an EEG experiment where the electric potential at the scalp surface is recorded at N different locations. Such a dataset can be written as a vector $\mathbf{H}(t)$, where component $H_i(t)$ is the time series from electrode i . On the other hand, for a given time point t , the N components of $\mathbf{H}$ represent a discrete spatial pattern of activity on the scalp surface. If N is sufficiently large, the potential can be described as a continuous function of space and time $H(x, t)$. For the spatially discrete and continuous cases, the decompositions read

$$\begin{aligned}\mathbf{H}(t) &= \sum_{i=1}^M \xi_i(t) \mathbf{v}^{(i)} H(x, t) \\ &= \sum_{i=1}^M \eta_i(t) g^{(i)}(x)\end{aligned}\quad (1)$$

where $\xi_i(t)$ and $\eta_i(t)$ are the time-dependent amplitudes that correspond to the pattern vectors and functions $\mathbf{v}^{(i)}$ and $g^{(i)}(x)$, respectively.

One application of such decompositions is the reduction of the size of the dataset, i.e., the sums are truncated at a value $M \ll N$. How well such a truncated decomposition represents the original data obviously depends on the choice of the basis vectors $\mathbf{v}^{(i)}$ or basis functions $g^{(i)}(x)$.

One of the most popular function sets to describe scalp potentials is the spherical harmonics (Nunez and Srinivasan 2006) given by

$$Y_l^m(\theta, \phi) = \sqrt{\frac{(2l+1)}{4\pi} \frac{(l-m)!}{(l+m)!}} P_l^m(\cos \theta) e^{im\phi} \quad (2)$$

where θ and ϕ are the polar and azimuthal angle, respectively, and P_l^m are the associate Legendre polynomials of degree l and order m . The spherical harmonics are orthogonal and normalized such that

$$\int_0^{2\pi} d\phi \int_0^\pi \sin \theta d\theta Y_l^{m'}(\theta, \phi) Y_l^m(\theta, \phi) = \delta_{ll'} \delta_{mm'} \quad (3)$$

where the asterisk “*” denotes the complex conjugate and δ represents the Kronecker delta.

The spatial patterns on the sphere for $l = 0 \dots 3$ and $m = 0 \dots 3$ are shown in Fig. 1 with the real and imaginary parts of the complex-valued functions on the right and left. The value for m is the number of minima and maxima in the azimuthal direction and Y_0^0 is a constant with a value of $1/4\pi$.

The spherical harmonics in space are closely related to the Fourier series in time as both are the eigenfunctions to an operator (The eigenfunctions of an operator are similar to the eigenvectors of a matrix. The application of a matrix to one of its eigenvectors simply scales the vector and nothing else, $M\mathbf{v} = \lambda\mathbf{v}$, where λ is a scalar, the eigenvalue. In the same way, an operator applied to one of its eigenfunctions results in the same function times a scalar $Of(x) = \lambda f(x)$.) that takes a second derivative. For the Fourier series in sine and cosine or complex exponentials, this takes the form

$$\begin{aligned} \frac{d^2}{dt^2} \cos \omega t &= -\omega^2 \cos \omega t & \frac{d^2}{dt^2} \sin \omega t \\ &= -\omega^2 \sin \omega t & \frac{d^2}{dt^2} e^{i\omega t} = -\omega^2 e^{i\omega t} \end{aligned}$$

Spatial Spectral Analysis, Fig. 1 The spatial patterns for the spherical harmonics with $l = 0 \dots 3$ and $m = 0 \dots 3$ plotted on a sphere with the real parts of the complex-valued functions on the *right* and the imaginary parts on the *left*

In space, in Cartesian coordinates, the Laplace operator, Δ , is simply the sum of the second derivatives, whereas in spherical coordinates, its form is more complicated. Explicitly, on a unit sphere, the angular part, $\Delta_{\theta\phi}$, applied to the spherical harmonics reproduces these functions times a constant

$$\begin{aligned}\Delta_{\theta\phi} &= \frac{1}{\sin\theta} \frac{\partial}{\partial\theta} \sin\theta \frac{\partial}{\partial\theta} \\ &\quad + \frac{1}{\sin^2\theta} \frac{\partial^2}{\partial\phi^2} \Delta_{\theta\phi} Y_l^m(\theta, \phi) \\ &= m(m+1) Y_l^m(\theta, \phi)\end{aligned}$$

In other words, the spherical harmonics $Y_l^m(\theta, \phi)$ are the eigenfunctions to the angular part of the Laplacian in spherical coordinates with eigenvalues $m(m+1)$.

Data-Dependent Basis: PCA

Instead of using a system of predefined basis vectors or functions, there are ways to calculate a basis from the dataset itself that is optimal in a certain sense to the specific data under consideration (Johnson and Wichern 2007, Jolliffe 2002). One such procedure is known as principal component analysis (PCA) (Other names for identical or very similar methods are Karhunen-Loève transform (KLT) or singular value decomposition (SVD)), where the basis is obtained as the eigenvectors $\mathbf{v}^{(i)}$ of the covariance matrix, C . Specifically, assuming a dataset of time series from N electrodes in EEG, the covariance matrix is an $N \times N$ matrix and calculated as

$$C_{ij} = \frac{1}{T} \int_0^T dt \{H_i(t) - H_i\} \{H_j(t) - H_j\} \quad (4)$$

where H_i and H_j are the mean values over time of $H_i(t)$ and $H_j(t)$, respectively. The eigenvalues of C , λ_i are a measure of the contribution of the corresponding eigenvector to the dataset. In many applications 90–95% of the entire variance is represented by a few of the eigenvectors corresponding to the largest eigenvalues. The

time series of the amplitudes for the eigenvectors are obtained as

$$\xi_i(t) = \mathbf{H}(t) \cdot \mathbf{v}^{(i)} = \sum_{n=1}^N H_n(t) v_n^{(i)} \quad (5)$$

As the covariance matrix is real, symmetric, and positive semi-definite, all eigenvalues are real and nonnegative, and the eigenvectors are mutually orthogonal. Moreover, the time series for the amplitudes $\xi_i(t)$ are also orthogonal and fulfill the relation

$$\int_0^T dt \xi_i(t) \xi_j(t) = \lambda_i \delta_{ij} \quad (6)$$

Principal component analysis is optimal in the sense that it minimizes the mean squared error between the dataset and its expansion for all truncation points. This means that if the decomposition is taken up to a point M and $\mathbf{v}^{(m)}$ are the eigenvectors corresponding to the M largest eigenvalues, the error E_M defined as

$$\begin{aligned}E_M &= \sum_{n=1}^N \int_0^T dt \left\{ H_n(t) - \sum_{i=1}^M \xi_i(t) v_n^{(i)} \right\}^2 \\ &= \text{Min} \forall M\end{aligned} \quad (7)$$

is a minimum independent of M , i.e., there is no set of M basis vectors that carry more of the variance of the dataset than the eigenvectors $\mathbf{v}^{(m)}$ of the covariance matrix.

Explicit Example

A short dataset representing 1 s from an EEG recording using a montage with 60 electrodes is shown in Fig. 2. The time series are arranged and color-coded in a topological layout corresponding to the spatial locations of the electrodes on the scalp surface (also shown in the insert). The same color coding for the time series is used in the butterfly plot in Fig. 3a, which also shows the spatial pattern of the potential at the maxima and minima. This dataset is decomposed by calculating the 60×60 covariance matrix as in Eq. 4,

Spatial Spectral Analysis, Fig. 2 Sample dataset of an EEG recording of 1 s from 60 different locations on the scalp surface as shown in the insert

Spatial Spectral Analysis, Fig. 3 The dataset and its decomposition using PCA. (a) Superposition of the time series (butterfly plot) with the color coding used in Fig. 2 together with topographical plots showing the spatial

patterns at the maxima and minima. (b) Spatial patterns representing the eigenvectors $\mathbf{p}^{(1-4)}$ that correspond to the four largest eigenvalues (left). Time-dependent amplitudes $\xi_{1-4}(t)$ and eigenvalues λ_{1-4} (right)

finding its eigenvalues and eigenvectors, and determining the amplitudes of the spatial patterns according to Eq. 5.

The results are shown in Fig. 3b with the four dominating spatial pattern, i.e., the eigenvectors corresponding to the four largest eigenvalues on the left and their time-dependent amplitudes on the right. The eigenvalues sum up to 0.9823,

which means that more than 98% of the total variance in the original 60-dimensional dataset is covered by these four patterns and their amplitudes.

Summary and Conclusions

Spatial spectral methods, in general, are used to perform a separation of a spatiotemporal signal

into patterns that depend only on space and corresponding time-dependent amplitudes, which may lead to a strong compression of the original dataset while keeping the relevant information. On the other hand, methods like PCA can also be used to detect artifacts (like bad electrodes in EEG) as they may get lumped into an individual pattern and can then be removed from the dataset. Aside from those representing artifacts, one should not attempt to interpret individual spatial patterns obtained by PCA as a manifestation of underlying separate sources because due to the way they are obtained (as eigenvectors of a real, symmetric matrix), they are mutually orthogonal, a constraint that is in general incompatible with activity patterns originating from different sources inside the brain. There are other decomposition techniques like independent component analysis (ICA) where the patterns do not have to be orthogonal but a further discussion of such methods is beyond the scope of this entry.

Spatial Temporal Spike Pattern Analysis

Moshe Abeles
The Leslie and Susan Gonda(Goldschmied)
Multidisciplinary Brain Research Center, Bar-Ilan
University, Ramat-Gan, Israel

Definition

Sequences of events that repeat several times are called *precise spatiotemporal patterns*. The

number of participating events is called the *complexity* of the patterns. The time precision with which the delays are measured is called the *time accuracy* of the pattern.

Examples

Suppose we have three parallel point processes (e.g., times of spiking of three neurons), among them, we find repeatedly an event from process A followed after t_1 seconds by an event from B and after t_2 seconds by an event from C, then the composite event

$$\begin{array}{c} A \\ | \text{ } _ t_1 _ B \\ | \text{ } _ _ t_2 _ _ C \end{array}$$

is called a precise spatiotemporal pattern and may be coded $\langle A, B, C; t_1, t_2 \rangle$. Its *complexity* is 3.

If t_1 and t_2 are taken at infinite resolution, the probability of observing it twice is zero. Therefore, some time accuracy (Δt) is associated with the pattern such that B occurred at $[t_1 \pm \Delta t/2]$ after A and C at $[t_2 \pm \Delta t/2]$ after A. Figure 1 illustrates such a precise spatiotemporal pattern.

Variations

In some works the value of Δt was varied and allowed to become longer, the longer is the delay t_i . In some works, just the order of events (disregarding the exact time interval between successive events) was also considered as a spatiotemporal pattern.

Detailed Description

History

Numerous publications mentioned observing precise spatiotemporal patterns in neuronal data (see Abeles and Gat 2001 for a partial list). The first ones to make a systematic search for such patterns were Dayhoff and Gerstein (1983a, b), who

Spatial Temporal Spike Pattern Analysis, Fig. 1 Example of a precise spatiotemporal pattern. Dot display of the pattern $\langle 2,5,6; 11, 101 \rangle$ that repeated 31 times. The precision was 3 ms. All dot rasters are aligned on the first spike in the pattern. Recording from the frontal cortex of a monkey performing a localization task of visual and auditory stimuli. The patterns tend to

appear after a visual stimulus (*down pointing arrows*) but are not tightly locked in time to the stimulus. Each neuron fired also other (seemingly random) spikes during and around the time of the patterns. This suggests that the precise timing is a network property (and not due to any internal processes of each of the neurons)

looked for repeating sequences of inter-spike intervals in the recorded activity of a single unit in the cat cortex. The first to systematically search for such patterns in parallel spike trains were Abeles and Gerstein (1988). Both reported significant excess. However, their methods for evaluating significance were criticized (Oram et al. 1999; Baker and Lemon 2000).

Meaning of Finding Precise Patterns

Existence of significant precise spatiotemporal patterns is taken as evidence that there is some mechanism that precisely controls the timing of events in the involved point processes. That relates to the question of how information is coded and transmitted within the cortex. Is it by firing rate, oscillations, precise synchrony, or delayed synchrony (► [Neural Coding](#))? For that the question whether there exists some mechanism that produces precise timing (and can read it) is so important. In a single neuron, precise firing patterns may be produced in a burst of

spikes, and periodic oscillations may be produced by internal pacemaker mechanism or in an oscillating network. The main interest in repeating spatiotemporal patterns is directed to cases that cannot be explained by precise time relations of external events, by intrinsic mechanisms of a single neuron, or by close to periodic oscillations of a network. When the above simple explanations do not apply, then one should assume that the patterns are the expression of some special neural networks that can produce them. The synfire chain model (Abeles 1982) and the polychronization model (Izhikevich 2006) are two such models.

Statistical Significance

Given enough data and large enough Δt , one expects to see many precise spatiotemporal patterns by chance. How can one decide whether the number of repetitions exceeds chance? Typically, one generates surrogate spike trains and looks for patterns there. If the data contains many more, it is assumed that they are significant. Numerous proposals of surrogates for looking for patterns exist

in the literature including the following: the individual point processes are inhomogeneous Poisson processes (Oram et al. 1999); they behave like gamma processes (Baker and Lemon 2000); two successive intervals in the same point process are not independent (Gerstein 2004); and a particular pattern $\langle A_0, A_1, A_2, \dots, A_n; t_1, t_2, \dots, t_n \rangle$ happens many more times when compared to patterns of the same events with slightly different times $\langle t_1, t_2, \dots, t_n \rangle$ (Abeles and Gat 2001) (► [Surrogate Data for Evaluation of Spike Correlation](#)).

The good way to examine the existence of precise timing was suggested by Geman and Bienenstock (Date et al. 2000; Hastopoulos et al. 2003). According to their suggestion, the null hypothesis is that there is nothing that controls the event timing below some accuracy W . Therefore, randomly teetering the event timing within W seconds should not affect any statistics that is derived from the involved point processes. Thus, one teeters the timing by W and computes the same statistics again and again forming a probability density function of the statistic for teetered data. If the value of the data statistic falls in the tail of this pdf, one can estimate the probability of the time accuracy of the data from the area of the tail. Figure 2 illustrates this process.

In theory, this idea is of limited usefulness. Any variation in the rate of events (e.g., a response of a neuron to a stimulus) will be “smeared” by such teetering. Thus, given enough data, it would be possible to detect significant variations by teetering. However, if the variations are slow relative to the window width W , it would take enormous amount of data to obtain significant differences. One should therefore be careful not to use this method when sharp transients of some property are expected. For example, inter-spike interval histograms may change abruptly from zero (during the refractory period) to some high level. Cross-correlations between pairs of spike trains may show a very sharp peak at zero lag (► [Unitary Event Analysis](#); ► [Correlation Analysis of Parallel Spike Trains](#)). Teetering spike times within W is equivalent to convolving the histogram with a boxcar kernel of width W . If the transition is sharp relative to W , significance may be found. This suggests a way to evaluate how much data would be needed before these effects will be significant.

Therefore, this method should not be used to detect significance for precise spatiotemporal patterns when the same point process participates more than once or when near zero delays between events in two point processes are included. The work of Shmiel et al. (2006) illustrates finding

Spatial Temporal Spike Pattern Analysis, Fig. 2 Distributions of patterns in randomly teetered data. *Red bar*, the number of repeating patterns in the data. *Blue histogram*, the distribution of the number of repeating patterns in data that was randomly teetered 100 times. The data is from the MEG recording of a subject that performed a task of following a musical meter. The

MEG data was converted to current dipoles in the cortex. From these the position of sharp (20 ms) peaks was detected and presented as parallel point processes. Data was sampled at 508/s and the precision was three samples. The teetering windows were 7, 5, and 3 samples from left to right respectively

accurate time relations between two spike trains even when W was 0.5 ms and all possible precautions were taken into considerations.

Spatiotemporal Energy Models

Wyeth Bair

Department of Biological Structure, University of Washington, Seattle, WA, USA

Synonyms

[Disparity energy model](#); [Motion energy model](#)

Definition

Spatiotemporal energy models were developed to explain the physiological properties of a class of motion sensitive neurons known as complex direction selective (DS) cells in the primary visual cortex (V1). These models are tuned to respond to energy within the spatiotemporal frequency spectrum of time-varying imagery, particularly to the spectral bands that are associated with specific directions of motion. This is accomplished using quadrature pairs of linear filters that are oriented both in space and in space-time. Spatiotemporal energy models are commonly used as the initial stages of higher-level models of motion, stereopsis, and form processing.

Detailed Description

Fundamental Example

The classical instance of a spatiotemporal energy model is the motion energy (ME) model (Adelson and Bergen 1985). It consists of two linear filters that have a quadrature phase relationship, meaning that one filter is shifted by ninety degrees with respect to the other. For example, if one filter is the product of a cosine function times a Gaussian, the other is the product of a sine times the same Gaussian, as follows:

$$h1(x, y, t) = \cos(f_s x + f_t t) e^{[-1/2(x^2 + y^2)/\sigma^2_s - 1/2t^2/\sigma^2_t]}$$

$$h2(x, y, t) = \sin(f_s x + f_t t) e^{[-1/2(x^2 + y^2)/\sigma^2_s - 1/2t^2/\sigma^2_t]}$$

where f_s , f_t , σ_s , and σ_t set the preferred spatial frequency (SF) and temporal frequency (TF) and the size of the filters in space and time, respectively. The output of the model is the sum of the squares of the two filter outputs.

Conceptual Development

Three insights were essential to the invention of spatiotemporal energy models. The first was that visual neurons could be modeled as linear filters and described in terms of their sensitivities to spatial and temporal frequencies within a sequence of images. By the end of the decade in which Hubel and Wiesel (1962) made the critical discovery that many V1 neurons were selective for the orientation, size, and direction of motion of simple bar stimuli, other experimentalists, in particular those using drifting sinewave grating stimuli, had begun theorizing that the visual system was in fact a spatial frequency analyzer containing independent, narrowband channels (Campbell and Robson 1968; Campbell et al. 1969; Blakemore and Campbell 1969; Maffei and Fiorentini 1973). Ultimately, it was established that responses of simple cells in V1 could, under limited conditions, be well described by the outputs of linear filters (Movshon et al. 1978).

The second essential insight was that visual motion, particularly rigid translation, creates orientation in space-time and that this can be detected by oriented space-time filters (Fahle and Poggio 1981; Watson and Ahumada 1983; Adelson and Bergen 1985). Here, theory preceded experiment, as the first clear demonstrations of spatiotemporal orientation in the responses of V1 neurons appeared several years later (Reid et al. 1987; McLean and Palmer 1989). The third essential insight was the use of the squared outputs of a quadrature pair of filters to demodulate the temporal response to moving stimuli (Adelson and Bergen 1985). This is related to the fact that $\cos^2 + \sin^2$ is a constant, and it allows the ME model to respond to a moving grating with a constant positive response and to a moving bar with a unimodal positive response. This was

important to capture the responses of complex, as opposed to simple, DS neurons.

Related Approaches

A contemporaneous approach to modeling DS neuronal responses began with the fundamentally nonlinear, correlation-style Reichardt motion detector (Reichardt 1957, 1961) and added appropriate linear filters at the front end, resulting in the elaborated Reichardt detector (ERD) model (van Santen and Sperling 1984, 1985). The ERD model has computational steps that are distinct from those of the ME model; nevertheless, in some forms, the final outputs of the two models are mathematically equivalent (Adelson and Bergen 1985). This demonstrates the close link between what are arguably the two historically most important models for direction selective neurons. An alternative approach that contrasts with the energy model was proposed by Watson and Ahumada (1985) in which the temporal modulation of the response, rather than being removed by squaring the outputs of quadrature filters, is retained and used to encode information relevant for downstream velocity estimation.

More recently, the spatiotemporal energy model has been modified and generalized to account for the responses of neurons that are selective for binocular disparity. The first binocular disparity energy (BDE) model (Ohzawa et al. 1990; Ohzawa 1998) was strictly spatial and consisted of separate pairs of quadrature filters for the left and right eyes. The preferred disparity is determined by a parameter that controls the offset of the filters across the two eyes, and the quadrature pair, followed by squaring, maintains the complex cell behavior. The BDE model has been unified with the ME model (Chen et al. 2001) to produce a set of spatiotemporal energy models that can account for both disparity and direction selectivity. These models continue to be the subject of active development as researchers attempt to account more accurately for response properties to an ever increasing set of visual stimuli (Read et al. 2002; Chen

and Qian 2004; Haefner and Cumming 2008; Peng and Shi 2010).

[Coherence and Granger causality spectral analysis](#); [Multivariate spectral analysis](#); [Oscillatory network activity analysis](#)

Definition

Spectral interdependency methods are a means of statistically quantifying the interrelationship between a pair of dynamic processes as a function of frequency or time period of oscillation. The measures of spectral interdependency are derived from the time series recordings of dynamic systems either by using autoregressive modeling (parametric method) or by using direct Fourier or wavelet transforms (nonparametric method). For a pair of multivariate stationary processes (1 and 2), there are three measures that characterize the spectral interdependency between these processes. They are total interdependence ($M_{1,2}$), Granger causality (one-way effect or directional influence from the first process to the second process, $M_{1 \rightarrow 2}$, or from the second to the first, $M_{2 \rightarrow 1}$), and instantaneous causality (measure of reciprocity, $M_{1,2}$). In general, the total interdependence is the sum of directional influences and instantaneous causality frequency by frequency ($M_{1,2} = M_{1 \rightarrow 2} + M_{2 \rightarrow 1} + M_{1,2}$) and is related to coherence (C_{12}) as $M_{1,2} = -\ln(1 - C_{12})$. These measures can also be estimated for nonstationary processes by using moving time-windowed autoregressive modeling or Fourier transformations or wavelet transformations. Coherence and spectral Granger causality are well-accepted measures in neuroscience to characterize frequency-specific interdependence between multiple time series from multisite neurophysiological recordings.

Detailed Description

Many processes in nature, including brain processes, have oscillatory motion, and the time series measurements of their activity are rich in oscillatory content, lending them naturally to spectral analysis. Spectral interdependency methods are used to study the relationship in the frequency domain between multiple processes from their simultaneously recorded time series signals. Consider a pair of zero-mean, stationary processes (1 and 2) in which simultaneously

measured time series at a sampling rate of f_s are represented as 1: $X_1(1), X_1(2), \dots, X_1(t), \dots$ and 2: $X_2(1), X_2(2), \dots, X_2(t), \dots$. The spectral interdependency measures as defined above are derived from the spectral matrix (S) and/or from the transfer function (H) and noise covariance matrix (Σ), which can be estimated by the parametric (Ding et al. 2006) or nonparametric approaches applied to these time series (Dhamala et al. 2008a, b). Brief mathematical derivations and descriptions of these interdependency measures (C_{12} , $M_{1,2}$, $M_{1 \rightarrow 2}$, $M_{2 \rightarrow 1}$, and $M_{1,2}$) are included below.

Directed transfer function (DTF) (Kaminski et al. 2001) and partial directed coherence (PDC) (Baccala and Sameshima 2001) are the accepted alternative measures of directional influence, equivalent to the measures for $M_{1 \rightarrow 2}$ and $M_{2 \rightarrow 1}$ as defined above. DTF is obtained from H and PDC from the Fourier transform of model coefficients in the parametric approach.

Parametric Approach

Jointly, X_1 and X_2 series can be represented as the following bivariate autoregressive (AR) models:

$$\begin{aligned} X_1(t) &= \sum_{j=1}^{\infty} a_{11,j} X_1(t-j) + \sum_{j=1}^{\infty} a_{12,j} X_2(t-j) + \varepsilon(t) \\ X_2(t) &= \sum_{j=1}^{\infty} a_{21,j} X_1(t-j) + \sum_{j=1}^{\infty} a_{22,j} X_2(t-j) + \eta(t), \end{aligned} \quad (1)$$

where ε and η are residual (one-step-ahead prediction) errors and are uncorrelated over time. After Fourier transforming the bivariate AR representation Eq. 1 and applying proper ensemble average, we obtain the following spectral density matrix S as a function of frequency (f):

$$S(f) = H(f) \Sigma H^*(f), \quad (2)$$

where $*$ denotes the matrix adjoint. Here, the noise covariance matrix Σ is computed from the residual errors $\varepsilon(t)$, $\eta(t)$ and the transfer function matrix $H(f)$ is constructed from the matrix inverse of the Fourier transforms of the coefficients as

$$\Sigma = \begin{pmatrix} \text{var}(\varepsilon) & \text{cov}(\varepsilon, \eta) \\ \text{cov}(\varepsilon, \eta) & \text{var}(\eta) \end{pmatrix} \quad (3)$$

$$H_{lm}(f) = \left(\delta_{lm} - \sum_{k=1}^{\infty} a_{lm,k} e^{-i2\pi f k} \right)^{-1},$$

where δ_{lm} is the Kronecker delta function with the matrix element index lm .

Nonparametric Approach

S , H , and Σ can also be estimated by using the nonparametric spectral methods (Dhamala et al. 2008a, b) without explicitly fitting the time series $X_1(t)$ and $X_2(t)$ in autoregressive models. In this approach, S is constructed by Fourier transforming X_1 and X_2 and properly averaging over ensembles usually with multitapers (Mitra and Pesaran 1999):

$$S_{lm} = \langle x_l(f) x_m(f^*) \rangle, \quad (4)$$

where lm is the index for time series and matrix element, $\langle \rangle$ represents averaging over ensemble, and X 's are the direct Fourier transforms of X 's. H and Σ can be derived from the minimum-phase factors of S :

$$H = \psi A_0^{-1} \quad (5)$$

$$\Sigma = A_0 A_0^T,$$

where T stands for matrix transposition, $\psi(e^{i\theta}) = \sum_{k=0}^{\infty} A_k e^{ik\theta}$ defined on the unit circle and $A_k = \frac{1}{2\pi} \int_{-\pi}^{\pi} \psi(e^{i\theta}) e^{-ik\theta} d\theta$.

Spectral Interdependence

The coherence function $C(f)$ is derived from the cross spectra normalized by the product of the individual auto spectra and measures the amount of interdependence (synchrony) as a function of frequency:

$$C(f) = \frac{|S_{12}(f)|^2}{S_{11}(f)S_{22}(f)}. \quad (6)$$

$C(f)$ is sensitive to both amplitude and phase relationships between processes at f and its value ranges from 0 (no interdependence) to 1 (maximum interdependence). $C(f)$ is related to Geweke's measure of total interdependence ($M_{1,2}$) (Ding et al. 2006).

$$M_{1,2}(f) = -\ln(1 - C(f)), \quad (7)$$

whose value ranges from 0 to infinity. The total spectral interdependence ($M_{1,2}$) is equal to the sum of Granger causality or directional influences (one-way effects, $M_{1 \rightarrow 2}$ and $M_{2 \rightarrow 1}$) and instantaneous causality ($M_{1,2}$) (Geweke 1982):

$$M_{1,2} = M_{1 \rightarrow 2} + M_{2 \rightarrow 1} + M_{1,2} \quad (8)$$

Here, directional influences between 1 and 2 are given by (Geweke 1982)

$$M_{1 \rightarrow 2}(f) = \ln \frac{S_{22}(f)}{\tilde{H}_{11}(f) \Sigma_{11} \tilde{H}_{11}(f)} \quad (9)$$

$$M_{2 \rightarrow 1}(f) = \ln \frac{S_{11}(f)}{\tilde{H}_{22}(f) \Sigma_{22} \tilde{H}_{22}(f)},$$

where $\tilde{H}_{11} = H_{11} + \sum_{12}^{12} H_{12}$, $\tilde{H}_{22} = \tilde{H}_{22} + \sum_{22}^{12} H_{21}$, and instantaneous causality $M_{1,2}$ is given by

$$M_{1,2}(f) = -\ln \frac{|S(f)|}{\left(\tilde{H}_{11}(f) \Sigma_{11} \tilde{H}_{11}(f) \right) \left(\tilde{H}_{22}(f) \Sigma_{22} \tilde{H}_{22}(f) \right)}. \quad (10)$$

Granger causality at low frequencies between a pair of cointegrated series depends only on a few statistically interpretable coefficients from the error correction model if Hosoya's spectral decomposition (Hosoya 1991) is used (Granger and Lin 1995).

The time-domain counterparts of these spectral measures in Eq. 8 are obtained by integrating the spectral measures over the entire frequency range as $\frac{2}{f_s} \int_0^{\frac{f_s}{2}} M(f) df$. The integral of total

interdependence measures the total amount of mutual information, and the other integrals are simply the respective time-domain measures of Granger causality.

Spectral Interdependency for Nonstationary Processes

The spectral interdependency measures can also be defined for nonstationary processes by treating their time series in sufficiently short windows as locally stationary processes. They can be estimated as a function of time and frequency by using

moving time-windowed autoregressive modeling (Liang et al. 2000), moving time-windowed Fourier transformations (Shiogai et al. 2012), or wavelet transformations (Dhamala et al. 2008a, b).

Numerical Examples

Here, we generate time series (500 trials) from jointly stationary and nonstationary processes and illustrate the estimation of coherence and Granger causality spectra using the parametric (P) and nonparametric (NP) approaches. We consider two interacting autoregressive processes,

Spectral Interdependency Methods, Fig. 1 Coherence (a, c) and Granger causality (b, d) spectra between stationary (a, b) and nonstationary (c, d) processes (1 and 2). Parametric (P) and Fourier transform-based nonparametric (NP) methods are used here to evaluate these quantities

(a, b) between the stationary processes. The wavelet transform-based time-frequency maps of coherence (c) and Granger causality (d) recover the time-varying nature of 2 to 1 coupling (shown on the right y-axis in d)

2: $\{X_2(t)\}$ driving 1: $\{X_1(t)\}$, similar to the network model considered in Dhamala et al. (2008b), where $X_1 = 0.55 X_1(t-1) - 0.8 X_1(t-2) + C(t)X_2(t-1) + \varepsilon(t)$ and $X_2(t) = 0.55 X_2(t-1) - 0.8 X_2(t-2) + \eta(t)$. Here, $(\varepsilon(t), \eta(t))$'s are independent white noise processes with zero means and unit variances, the sampling rate is considered to be 200 Hz, and the coupling strength $C(t)$ remains 0.25 for time t in the stationary condition and slowly changes from 0.25 to 0 around $t = 2$ s in the case of nonstationary processes. P and NP approaches agree well in coherence and Granger causality spectra (Fig. 1a, b). Morlet wavelet transform-based method yields complete time-frequency maps of coherence (Fig. 1c) and Granger causality (Fig. 1d), consistent with the trend of the 2 to 1 coupling as shown on the right side of Fig. 1d.

Extensions of Spectral Interdependency Methods

As an extension of the ordinary coherence described above, block coherence (Nedungadi et al. 2011) can estimate coherence spectra between pairs of nonoverlapping time series. Conditional Granger causality (Geweke 1984; Hosoya 2001) measures directional influences between two processes eliminating the effect of a third process, thereby distinguishing between direct and mediated causality (Ding et al. 2006; Dhamala et al. 2008b). The multivariate version of the spectral Granger causality between two processes makes use of this idea of eliminating the causal effect from all other interrelated processes as an extension of the conditional Granger causality defined for three processes.

Applications in Neuroscience

Spectral interdependency measures have been instrumental in attempts to understand the relationships between oscillatory brain processes at various spatial scales from multisite brain activity recordings. Coherence is widely used in neuroscience (Siegel et al. 2012; Roberts et al. 2013). The

insights provided by this measure have even led to the “neuronal communication through coherence” hypothesis (Fries 2005; Roberts et al. 2013). Spectral Granger causality and equivalent directional measures have been used in a variety of brain signal recordings, such as local field potentials, EEG, MEG, and fMRI, in animals and humans (see Bressler and Seth 2011; Friston et al. 2012 for reviews). Because of the unknown theoretical distributions of coherence and spectral Granger causality, establishing statistical significance in these measures derived from experimental time series requires data resampling (surrogate) methods such as jackknifing (Bokil et al. 2010), bootstrapping, and random permutation (Seth 2010).

 école Normale Supérieure, Paris, France

Synonyms

Frequency tuning curves; Iso-intensity response curves; Spectrotemporal response fields

Definition

The spectrotemporal response field (STRF) of an auditory neuron is a time-frequency measure of the dynamic responses of an auditory neuron to impulsive energy delivered at various

frequencies. As such, it gives simultaneously two types of information about the neuron. The first is its frequency tuning, or more specifically which frequencies excite the cell best and which inhibit it. The other is the nature of its temporal response, i.e., whether it is sustained in time or is rapidly adapting. This measure is linear and takes the stimulus spectrogram as its input and hence is often found to be useful in predicting responses of a neuron to unseen stimuli.

Detailed Description

The Value of the STRF

A key requirement in the study of sensory nervous systems is the ability to characterize effectively neuronal response selectivity. In the visual system, striving for this objective yielded remarkable progress in understanding the functional organization of the visual cortex and its implications to perception. For instance, the discovery of ordered feature representations of retinal space, color, ocular dominance, orientation, and motion direction in various cortical fields has instigated vast studies into the anatomical bases of this organization, its developmental course, and the changes it undergoes during learning or following injury. In the primary auditory cortex (A1), response selectivity of the neurons (also called their *response fields*) is ordered topographically according to the frequency they are most tuned to, an organization inherited from the cochlea. Beyond their tuning, however, A1 responses and response fields exhibit a bewildering variety of dynamics, frequency bandwidths, response thresholds, and patterns of excitatory and inhibitory regions. All this has been learned over decades of testing with a large variety of acoustic stimuli (tones, clicks, noise, and natural sounds) and response measures (tuning curves, rate-level functions, and binaural maps).

Distinguishing the STRF

A response measure that has proven particularly useful beyond the feature-specific measures

enumerated earlier is the notion of a generalized *spatiotemporal*, or equivalently for the auditory system, the *spectrotemporal response field* (STRF). It is distinguished from other measures by its broader descriptive power (encompassing both dynamics and spectral selectivity) and its relatively noncommittal nature (not requiring too much prior knowledge such as frequency tuning or threshold). In the last two decades, the STRF has become widely employed in all sensory systems (Hochstein and Shapley 1976; De Valois and De Valois 1988; Arun et al. 2006; Aertsen and Johannesma 1981; DeAngelis et al. 1995; Gosselin and Schyns 2002), and especially in the auditory system where it had found its original promise, development, and examination of its value and liability (Arun et al. 2006; Aertsen and Johannesma 1981; de Boer 1967; de Boer and de Jongh 1978). The STRF has primarily been viewed as a linear characterization of the complex stimulus-response transformations seen in sensory neurons. However, there are well-understood limitations of the STRF ability to capture all the essential details of a sensory neuron's response. These stem from the existence of a host of known nonlinearities such as spiking threshold, rate saturation, and synaptic-depression that can complicate the interpretation of the STRF and render its representation stimulus dependent or meaningless. Nevertheless, the utility of the STRF has inspired deeper and broader examination of its constraints and pitfalls and ways to circumvent them (David et al. 2006; Christianson et al. 2008; Atencio et al. 2008; Nagel and Doupe 2008) or even exploit them to learn more about the nonlinearities in the system (Theunissen et al. 2000; Ahrens et al. 2008; Klein et al. 2006).

Using the STRF

The STRF concept has proven valuable in the understanding of auditory cortical processing and its applications in audio systems ranging from speech and speaker recognition to enhancements of speech signals and cochlear implants. Their first valuable contribution has

been to provide an effective summary of the representation of sound features in the primary auditory cortex (Theunissen et al. 2000; Atencio et al. 2008; Shamma et al. 1995). A key finding has been the realization that the huge variety of auditory cortical responses in frequency tuning, dynamics, and other features has inspired models of auditory processing that view the cortex as a “multiscale” spectrotemporal analyzer that decomposes the signal into a rich representation that can be effectively harnessed for a variety of applications (Chi et al. 2006). For example, complex signals such as speech and music can be analyzed in this cortical model to understand how phonetic information is represented (Mesgarani et al. 2008) or how timbres of different musical instruments are encoded (Patil et al. 2012). The uniqueness of the representation of the different types of signals allows us further to separate the speech from interfering noise, to detect the presence of speech compared to no speech (Mesgarani et al. 2005), and to separate multiple speakers (Elhilali and Shamma 2008).

STRF and Plasticity

STRFs have proven valuable in plasticity and developmental studies as a summary of a neuron's response properties *even if incomplete*. The reason is that in many cases, it is not the completeness of the representation that is of interest but rather *how* the (admittedly incomplete) representation changes during behavior or learning. In this role, the STRF has demonstrated a robustness and versatility that was not initially appreciated. For instance, auditory cortical STRFs often provide an estimate of the *relative* sensitivity of a neuron to different frequencies and temporal dynamics. Therefore, when examining the effects of attention and learning, changes in neuronal responsiveness are often unpredictable in their dynamics or spectral configurations or are very small and augment already very noisy responses. The STRF counters both of these challenges. Thus, by virtue of its generalized nature (not being specific to a particular feature or response dimension),

changes in the neuronal sensitivity in one of multiple dimensions can readily be spotted and characterized (Fritz et al. 2003). Furthermore, these response changes are often very difficult to discern or interpret (as spectral or temporal changes) in the firing rates themselves. STRFs by their nature are simultaneous *relative* measures of a neuron's responsiveness to many frequencies and dynamics. Consequently, the effect of attention and learning (and behavior in general) is often seen as changes in the STRF shape that can be readily interpreted as changes in the relative sensitivity of the neuron to different frequencies (Fritz et al. 2005a) or in the temporal parameters of the STRF such as its latency (Fritz et al. 2005b) (Fig. 1).

Forward and Inverse STRF

Another interesting use of the STRFs is in characterizing global response properties of a large population of cells or cortical areas for the purpose of summarizing its representational properties and how that may change due to learning and plasticity. Specifically, in many situations, cortical neurons encode considerable details about the underlying sensory stimuli, and the encoded information is likely to change with stimulus context and behavioral conditions in a manner that is difficult to discern across large sets of single neuron data because of the complexity of cortical receptive fields. STRFs help overcome this problem because they

Spectrotemporal Receptive Fields, Fig. 1 Example of an STRF that showed spectral and temporal task-related plasticity in successive tasks. The spectral task was performed first, with a target tone of 2 kHz. The STRF obtained during spectral task behavior displayed an expansion of both excitatory fields towards the target frequency. The STRF returned to its original pre-passive shape following behavior. Shortly after the spectral task, the animal was presented with the temporal task, in which it had to discriminate reference click trains of 12 Hz from target

click trains presented at 30 Hz. In contrast to the plasticity observed during the spectral task, in the temporal task the excitatory field of the STRF became narrower. This narrowing of the STRF persisted following behavior. Persistent plasticity has also been described previously (Fritz et al. 2003). (From Abstract #377, ARO 2013, *Laminar Recordings of Task-Related Receptive Field Plasticity with Multisite Depth Electrodes in the Primary Auditory Cortex (A1) of the Behaving Ferret*, by Elgueda D., B Englitz, M Locastro, M Elhilali, S Shamma, and J Fritz)

facilitate methods of stimulus *reconstruction* to study how complex sounds are encoded in AI. In such a method, measured STRFs are used to *invert* the responses and hence map population responses to an estimate of the stimulus spectrogram (Mesgarani et al. 2009). This enables one to perform a direct comparison between an original stimulus spectrogram and its reconstruction following learning or from responses during a behavioral paradigm. In fact, by estimating the fidelity of such reconstructions using generalized spectrally and temporally modulated noise stimuli, one can determine the range over which AI neurons can faithfully encode such spectrotemporal features. Finally, contrasting stimulus reconstructions under different behavioral states can reveal a novel view of the rapid changes in spectrotemporal response properties induced by different attentional and motivational states.

Updating the STRF

There is much ongoing research to develop new STRF measurement procedures and structures and to combine them with new methodologies that go beyond the simple ways employed earlier. For instance, generalizing the STRFs to include nonlinear phenomena (Atencio et al. 2008; Christianson et al. 2008; Nagel and Doupe 2008), inhibitory interactions (Schinkel-Bielefeld et al. 2012), and more flexible structures are among the goals being pursued. Also, STRFs are now being regularly estimated with a variety of specialized complex sounds such as bird vocalizations and speech (David et al. 2007; David et al. 2009; Theunissen et al. 2000), measurements that yield STRFs that are tailored to describe more faithfully cortical responses to these sounds. Furthermore, STRFs have now transcended their initial use in single unit recordings and are currently being widely used as a tool to summarize responses in human subjects recorded with fMRI (Zatorre and Belin 2001), MEG (Ding and Simon 2012), EEG (Power et al. 2011), and ECoG (Mesgarani and Chang 2012).

Speed-Accuracy Tradeoff

Rafal Bogacz

Department of Computer Science, University of Bristol, Bristol, UK

Definition

In many decision tasks, humans and animals cannot simultaneously improve both speed and accuracy of choices (Wickelgren 1977). If subjects are required to be faster, they become less accurate, and conversely, when they are more accurate, they become slower. This inverse relationship between the speed and the accuracy of choices is known as the speed-accuracy trade-off (SAT).

Detailed Description

SAT Results from the Accumulation of Noisy Information

SAT is produced in many models of decision making, but to motivate these models, it is helpful to first briefly review a specific example of a task used for studying the neurobiology of perceptual

decision making. Neural bases of decision making have been studied in a simple task in which a subject is presented with a stimulus consisting of dots moving left or right and on each trial has to make an eye movement in the direction of the movement of the majority of dots. A brain area critical for this task is a part of visual cortex specialized in motion processing (known as V5 or MT), where different neurons are selective for different directions of motion and respond when motion in their preferred direction is present in their receptive field (Britten et al. 1992). These neurons provide information that could be used to make a decision, but the activity of these sensory neurons is noisy due to the noise present in the stimulus and the stochastic nature of neuronal firing. Experimental data suggest that to average out this noise, the output from sensory neurons selective for a particular stimulus is integrated by the frontoparietal neurons selective for a corresponding response (Gold and Shadlen 2007). This is suggested by an observation that the neurons selective for a particular response gradually increase their activity within a trial with a rate that depends on the activity of corresponding sensory neurons. It has been further observed that the movement is initiated whenever the activity of these integrator neurons reaches a certain threshold level (Gold and Shadlen 2007).

Computational models describing the above decision process range from abstract mathematical models, e.g., Ratcliff (1978), to detailed spiking models, e.g., Furman and Wang (2008). The simplest of these models is an abstract race model in which two integrators accumulate independently sensory inputs from two corresponding sources, and the choice is made when the activity of any integrator reaches a threshold (Vickers 1970). The sources of input are noisy, but one of them provides an input with a higher mean, and the choice is considered correct, when the integrator accumulating the information from this source is the first to reach the threshold. The integration process averages out the noise present in the inputs; thus, the longer the period of integration, the higher the probability that the “correct” accumulator wins the race. The ability to trade speed for accuracy in the model arises due to the assumption that subjects are able to vary the distance between the baseline

Speed-Accuracy Tradeoff, Fig. 1 Simulated activity of accumulators in the race model. In the simulation the accumulator corresponding to *dark blue line* received input from a source with a higher mean than the accumulator corresponding to *light blue line*. Green and red lines indicate two possible positions of decision threshold and circles the times when the decision would be made. (Reproduced from Bogacz et al. (2010) with permission from Cell Press)

level of the integrators at the start of the trial and the threshold, as illustrated in Fig. 1. When this baseline to threshold distance is short, the decisions are on average faster but less accurate, whereas when the baseline to threshold distance is long, it takes on average longer to reach the threshold, but the choice is made on the basis of a larger amount of input, so it is more likely to be correct.

Speed Emphasis Increases Baseline Activity

In many computational models, like the race model discussed above, speed and accuracy depend on the baseline to threshold distance: thus, faster choices may be achieved either by lowering the decision threshold or by increasing the initial level of activity of the integrator neurons. Experimental data suggest that the latter mechanism is employed by the brain. Increased baseline with speed emphasis was first suggested by imaging studies that observed higher activity in several decision-related areas before the onset of trials on which participants were required to be fast (Forstmann et al. 2008; Ivanoff et al. 2008;

van Veen et al. 2008). More recently this suggestion was confirmed by a study (Heitz and Schall 2012) in which monkeys were trained to make saccadic choices in three conditions: fast, neutral, and accurate (in the fast condition they were rewarded only if the correct response was made before a certain deadline). Recordings of the activity of neurons from frontal eye field (FEF) in this task revealed that their activity before stimulus onset was indeed higher in the fast than in the neutral condition. Furthermore, a computational model of subcortical neurons receiving input from FEF, which was constrained by the data from the above experiment, suggested that the threshold activity these downstream neurons needed to reach for the response to be initiated was the same for all three conditions (Heitz and Schall 2012).

Control Over Speed and Accuracy

Several detailed theories have been proposed on how the speed and accuracy of choices are controlled in neural decision circuits in cortex (Furman and Wang 2008; Roxin and Ledberg 2008) and basal ganglia (Lo and Wang 2006; Frank et al. 2007; Forstmann et al. 2010). These models describe what inputs or plastic changes in the corticobasal-ganglia circuits could result in the increased baseline activity of cortical integrators with speed emphasis (see previous section), and these theories have been reviewed in more detail by Bogacz et al. (2010). Although these proposed mechanisms are very different from one another, it is conceivable that multiple mechanisms operate in parallel.

Optimal Speed and Accuracy

The selected combination of speed and accuracy of choices influences the reward rate, i.e., the number of rewards per unit of time, in many natural foraging tasks and experimental paradigms. For example, consider a simple paradigm in which on each trial a subject has to judge the direction of movement of the majority of dots (as described earlier) and receives rewards for

correct responses and no penalties for errors, and after each response there is a fixed delay until the beginning of the next trial. In this paradigm the optimal combination of speed and accuracy maximizing the reward rate depends on task parameters (Bogacz et al. 2006). For instance, when the dots move completely randomly, in order to maximize the reward rate, the subject should respond as quickly as possible (as the accuracy cannot be improved by inspecting the stimulus), whereas when substantial fraction of dots move coherently, the subject should take more time to respond more accurately. Experimental evidence suggests that humans indeed adapt their speed and accuracy to improve their reward rate (Simen et al. 2009), especially when given more practice (Balci et al. 2011).

In the above paradigm, if the difficulty of all trials is constant, reward rate is maximized in computational models by setting the baseline to threshold distance to an appropriate constant throughout the trial (Bogacz et al. 2006). However, when the difficulty varies between trials, the distance should change within a trial to maximize reward rate. For example, when a substantial amount of time has elapsed within a trial and the choice has still not been made, the subject may infer that this is a very difficult trial, so it is better to force a decision and move on to the next trial. Methods for estimating the optimal time course of the threshold parameter of decision models have been described (Deneve 2012; Drugowitsch et al. 2012). However, recall that in mathematical models speed and accuracy can be adjusted by varying either the threshold or the baseline level of activity, and experimental data indicate that when difficulty varies between trials, the levels of activity of integrator neurons increase within a trial, eventually forcing a fixed decision threshold to be reached (Churchland et al. 2008).

Spike Time Response Curve

Theoden I. Netoff
 Department of Biomedical Engineering,
 University of Minnesota, Minneapolis, MN, USA

Definition

The spike time response curve (STRC) is a measure of how a stimulus affects the timing of a neuron's action potential. Specifically, in a periodically firing

Spike Time Response Curve, Fig. 1 *Left panel*, a pyramidal neuron in the hippocampus is recorded and stimulated using whole-cell patch clamp. Voltage traces (*top*) and stimulus current (*below*) are plotted from three segments of data. The first interspike interval is unperturbed in all three traces, and interspike intervals are almost identical. In the second interval, a stimulus is applied. The *solid line* shows the unperturbed recording, and the *dotted* and *dashed lines* show recordings where a synaptic-like

stimulus waveform is applied, at a time just after the neuron spikes (*dotted*) and in the *middle* of the period (*dashed*). *Right panel*, the spike time response curve is generated by plotting spike time advance (STA) from the unperturbed interspike interval (150 ms in this case) against the time that the stimulus was applied since the last spike. A polynomial function is fit to the mean and the standard deviation of the data (This figure is modified from Netoff et al. (2005))

Spike Time Response Curve, Fig. 2 Phase response curve compared to STRC. A PRC (*left*) and an STRC (*right*) are measured from a computational model of a neuron at different amounts of applied current. As the

applied current increases, the interspike interval decreases. The PRC is normalized to the change in the unperturbed interspike interval, while the STRC is not. Both graphs represent the same data but with different axes

neuron, the STRC is a measure of the change in the interspike interval given the time of the stimulus pulse since the last action potential. An example of an STRC measured from a pyramidal neuron in the

hippocampus is shown in Fig. 1. The STRC is closely related to the phase response curve (PRC); the difference is that the STRC is not normalized by the period of the neuron.

Detailed Description

An example where the PRC and the STRC provide different information is when comparing stimulus responses at different firing rates of the neuron. Figure 2 shows the same data plotted as a PRC and as an STRC from a model neuron, the $I_{NaP,K}$ model (Izhikevich 2007). As current applied to the neuron increases, the interspike interval shortens. It can be seen at higher current and shorter ISIs, the PRC peak of the PRC shifts to the right. However, when plotted as an STRC, the peak shifts earlier in time. The amplitude of the phase advance is also normalized by the interspike interval. It can be seen that the difference in the peak from the smallest to biggest PRC is about sixfold, while in the STRC, the difference between the smallest peak spike advance and the largest is a twenty-fold difference. As stated above, the STRC retains information about time intervals, whereas the PRC is normalized by the intrinsic period. It is necessary to retain the information about time intervals in order to predict the synchronization properties of periodically driven or reciprocally coupled oscillatory neurons, as described in the entry on ► “Pulse-Coupled Oscillators” (Netoff et al. 2005; Oprisan et al. 2003; Glass and Mackey 1988).

Spike Train

Robert E. Kass

Carnegie Mellon University, Pittsburgh, PA, USA

Definition

A spike train is a sequence of recorded times at which a neuron fires an *action potential*. When the voltage drop across a neural soma or axon membrane is recorded, intermittent pulses of roughly 100 mV over 1–2 ms are observed – these are action potentials or “spikes.” On a behavioral time scale of several hundred milliseconds, each spike may be considered to occur at a single point in time. Sequences of such spike times form spike trains. The total duration of a recorded spike train can range from less than a second to many minutes or even, in chronic recordings, to many days. Spike trains are considered to be the primary mode of information transmission in the nervous system.

Detailed Description

When action potentials are recorded repeatedly from a neuron in response to changing stimuli (or while an organism produces changing behaviors), they maintain a relatively consistent shape. However, the pattern of spike times varies as the stimulus changes. Most prominently, the rate at which spikes occur, the firing rate (FR), varies with conditions. When firing rate is defined in terms of the number of spikes that occur over a time interval of length Δt (such as $\Delta t = 500$ ms), using

$$FR = \frac{\text{number of spikes}}{\Delta t}, \quad (1)$$

this phenomenon of firing rate varying with stimulus is called *rate coding*. While analysis of neural activity in terms of varying firing rates, as defined in Eq. 1, is useful in many contexts, more subtle alterations of the pattern of spike times also occur

and these, too, may convey information. For example, the lengths of gaps between spikes, known as inter-spike intervals (ISIs), often vary substantially across an observed spike train. In principle, a neural communication “code” could carry enormous amounts of information in the specific patterns of spike times, but even in highly controlled in vitro preparations, repeated injection of the same time-varying current can lead to varying spike times, due to the stochastic behavior of ion channels and related sources of noise. Furthermore, synaptic noise is introduced at multiple connections across a neural network. Thus, a good deal of the irregularity of ISIs observed in many parts of the nervous system (especially, in cortex) may be unrelated to any stimulus or behavior. The problem of *neural coding* is to determine the ways that patterns of spike times convey information in particular contexts, possibly extending beyond rate coding. For this purpose, spike trains are subjected to statistical methods of data analysis.

In probability and statistics, irregular sequences of event times are modeled as *point processes*. If we start at time $t = 0$ and let $X_1, X_2, \dots$ be a sequence of random variables representing the ISIs, then the time of the j th spike is given by $S_j = \sum_{i=1}^j X_i$ and the sequence $S_1, S_2, \dots$ forms a point process. In practice, point processes representing spike trains are considered only over some finite interval of time $[0, T]$.

The oldest and most basic model for spike trains is the *integrate-and-fire model*, according to which a neuron is equivalent to an electrical circuit involving a resistor and a capacitor in parallel, together with an input current; the neuron fires whenever the voltage reaches a threshold, then it resets to a fixed resting potential. A component of the input current may be used to represent stochastic synaptic activity. This idea, and many variations on it, is commonly used to generate artificial spike trains in computational studies (Gerstner and Kistler 2002). The resulting spike trains follow point processes and, under simplifying assumptions, can be subjected to theoretical analysis. For example, when excitatory and inhibitory inputs are conceptualized (in the theoretical limit) as Brownian motion, the ISI

distribution may be derived analytically (Tuckwell 1988), and it turns out that certain features of this ISI distribution bear a striking qualitative resemblance to corresponding features of observed spike trains.

Point process representations of spike trains are governed by a theoretical instantaneous firing rate. If we replace the spike count in the numerator of Eq. 1 by its theoretical counterpart, the expected spike count, and then pass to the limit as $\Delta t \rightarrow 0$, we obtain

$$FR(t) = \lim_{\Delta t \rightarrow 0} \frac{P(\text{spike in } (t, t + \Delta t))}{\Delta t}. \quad (2)$$

(For small intervals Δt there is at most 1 spike and the expected count is equal to the probability of spiking.) However, the definition in Eq. 2 omits any mention of both the spiking behavior prior to time t and the experimental context. For instance, immediately after a neuron fires a spike, the probability of the neuron firing again is greatly reduced – this is known as the refractory period. If we write all relevant variables that affect the probability of a neuron firing (including the time of the most recent previous spike) as a vector x_t , we instead obtain the more explicit definition of neural firing rate:

$$FR(t|x_t) = \lim_{\Delta t \rightarrow 0} \frac{P(\text{spike in } (t, t + \Delta t)|x_t)}{\Delta t}. \quad (3)$$

Acknowledging that the numerator of Eq. 3 may involve complicated functions of stimuli, prior spiking patterns, and other variables, a statistical model for spike trains involves two things: (i) a simple, universal formula for the probability density of the spike train in terms of the instantaneous firing rate function defined in Eq. 3 and (ii) a specification of the way the firing rate function depends on the variables x_t (the numerator of Eq. 3). This representation provides a framework that may be called *point process regression* because it relates the specific pattern of spike times, i.e., the spike train, to variables collected as x_t . The full battery of modern statistical machine learning methods may then be applied to the problem of neural coding.

The simplest point process regression models take a special form known in the statistics literature as *generalized linear models* (GLMs). In computational neuroscience the term GLM may refer to any type of point process regression model.

Definition

A “spike train distance” is a means for comparing two sequences of stereotyped events. The term “spike metric” refers to a spike train distance that, additionally, has the formal mathematical properties of a metric. Spike train distances have broad application in neuroscience, since the action potentials emitted by a neuron or set of neurons can be regarded as a sequence of stereotyped events; we briefly survey these applications here.

Detailed Description

Spike train distances are rules for assigning a notion of distance, or dissimilarity, to pairs of event sequences. In contrast to most quantitative approaches to the analysis of scientific data, the framework of spike train distances does not make the implicit assumption that the objects of interest (i.e., the event sequences) can be thought of as vectors. In many cases, including the earliest examples of spike train distances (van Rossum 2001; Victor and Purpura 1996, 1997), these distances also satisfy the formal mathematical requirements to be a “metric” (see below). In this case, the event sequences may be considered elements in a “metric space.” A metric space is a topological space that is more general than a vector space. A metric space must have a notion of distance, but it need not have coordinates, nor allow for addition, scalar multiplication, or the measurement of angles.

Two considerations give this general framework a special flavor when applied to neural data. The first consideration is mathematical: for event sequences, it is natural to think of the topology as combining a discrete component with a continuous component. The discrete component is that the number of events in a spike train must be an integer; the continuous component is that each of these events can occur across a continuum of times. The second consideration is biological: much is known about the physiology of neurons and neural circuits, and spike train distances are typically designed with the goal of capturing the

biologically significant aspects of neuronal activity.

As detailed below, two contrasting ideas concerning the biological meaning of a spike train serve as anchor points: (a) the firing events in a spike train might serve primarily as a means to represent an underlying firing rate vs. (b) the times of these firing events might have individual significance, enabling neural computations to be based on coincident firing events across neurons and other aspects of fine temporal structure.

Notation

A spike train – the sequence of action potentials emitted by one or more neurons – is formalized as a sequence of stereotyped events, called spikes, that occur during a fixed observation period $[0, T]$. That is, a spike train A is represented by an ascending sequence of real numbers $t_1^A, \dots, t_{M(A)}^A$ in $[0, T]$, where t_j^A (or simply t_j) is the time of occurrence of the j th spike and $M(A)$ is the total number of spikes (which may be 0).

The above applies to a setting in which all spikes originate from a single neuron or in which the identity of the neurons that generate the individual spikes is not distinguished. It is readily extended to a setting in which the neural activity arises from R different neurons, and the neuron of origin of each event is known: the sequence of times $t_1, \dots, t_{M(A)}$ is associated with a sequence of labels $a_1, \dots, a_{M(A)}$, each drawn from a set of tags $\{1, \dots, R\}$. Thus, spike trains are regarded as a sample drawn from a **point process** (activity of one neuron) or a **labeled point process** (activity of several neurons).

Formal Definition

A spike train distance is a mapping D from the set of spike trains to the nonnegative real numbers that meets the three requirements of a topological **metric**:

Non – negativity: $D(A, B) \geq 0$ and

$$D(A, B) = 0 \text{ only if } A = B \quad (1)$$

$$\text{Symmetry: } D(A, B) = D(B, A) \quad (2)$$

$$\begin{aligned} \text{Triangle inequality: } D(A, C) \\ \leq D(A, B) + D(B, C) \end{aligned} \quad (3)$$

The symmetry property (Eq. 2) and the triangle inequality (Eq. 3) are critical to give the metric the properties that one expects from a distance based on paths between points. Specifically, the symmetry property means that the shortest path between two points does not depend on the direction of travel, and the triangle inequality means that the shortest path between two points (A and C) cannot be any longer than a path that is constrained to stop at a particular intermediate point B . However, the nonnegativity property (Eq. 1) is less crucial and is frequently relaxed to omit the “only if” clause – in which case, D is formally a **pseudometric**. In this case, the space of spike trains can be partitioned into equivalence classes of spike trains that are at distances of zero from each other, and D acts as a metric on these equivalence classes. The “spike count distance,” formalized following Eq. (11), is a simple example of a pseudometric; spike trains with the same number of spikes fall into an equivalence class.

Constructing Spike Train Distances

Spike train distances can be organized into several families. The most straightforward family is based on embedding: spike train distances are defined by mapping the spike trains into a vector space and then adopting the vector space distance. Since the vector space distance is a metric, the resulting spike train distance is also guaranteed to be a metric.

However, spike train distances need not be derived from distances in vector spaces. In cost-based distances, a set of simple transformations of spike trains is specified, along with their (nonnegative) costs. The spike train distance is then defined as the minimal total cost of transforming one spike train into another. Because the distance is defined in terms of a minimum cost

path of transformations, these distances are guaranteed to be metrics. Other families of distances include time-resolved and timescale-independent spike train distances, described below. These constructs, while intuitively distances, do not meet the formal requirements of a metric.

Spike Train Distances Based on Embedding

In the embedding construction, spike trains are first mapped into a **normed vector space** V via a mapping f . Since the vector space norm $\|u\|$ provides a metric on vectors via $D(u, v) = \|u - v\|$, mapping spike trains into vectors yields a metric on the spike trains:

$$D(A, B) = \|f(A) - f(B)\| \quad (4)$$

The nature of the mapping f from the space of spike trains to the vector space is critical. Typically, this mapping respects an additive structure on the spike trains: that is, if $A + B$ denotes the spike train that results from superimposing A and B (with suitable provision made for coincident spikes), then $f(A + B) = f(A) + f(B)$. For such embeddings, then resulting metric is unchanged by parallel translation:

$$D(A + C, B + C) = D(A, B) \quad (5)$$

Spike train distances in this class generally emphasize either the continuous aspect of spike train topology or its discrete aspect. The family of distances introduced by van Rossum (van Rossum 2001) is a prototypical example of the former. We consider first the case of an unlabeled spike train, which here is regarded as a sequence of delta functions. The target vector space consists of scalar functions of time (considered as a continuous variable), and the embedding f consists of a convolution by a kernel function $K(t)$:

$$f(A)(t) = \int_{-\infty}^{\infty} K(t - \tau) \sum_{j=1}^{M(A)} \delta(\tau - t_j^A) d\tau \quad (6)$$

Since the mapping in Eq. (6) from the spike train A to the vector space element $f(A)$ is linear, it follows that the resulting metric, defined by

Eq. (4), is unchanged by parallel translation (as in Eq. 5).

Typically the kernel function K in Eq. (6) includes a parameter that expresses the temporal resolution of the comparison between two spike trains, e.g.,

$$K(t) = \begin{cases} \frac{1}{t_0} e^{-t/t_0} & , t \geq 0. \\ 0, & \text{otherwise} \end{cases} \quad (7)$$

If spikes in train A and train B are matched within this resolution, i.e., if $|t_j^A - t_j^B| \ll t_0$, then the spike train distance between A and B will be small. Gaussians, boxcars, and similar nonnegative windowing functions are also reasonable choices for K . These embedding functions are conventionally used in conjunction with an L^p norm for the target vector space,

$$\|f(A)\| = \left(\int_{-\infty}^{\infty} |f(A)(t)|^p dt \right)^{1/p}, \quad (8)$$

usually with $p = 2$ (the Euclidean norm). Thus, the net result of a linear embedding followed by the vector space norm provides a Euclidean geometry on spike trains.

To extend this kind of spike train distance to the multineuronal setting (R labeled neurons), the target vector space is taken to be vector-valued functions of time (Houghton and Sen 2008), and the norm is the L^2 -norm on the space of vector-valued functions. To define the embedding function f , vectors $\vec{v}_l$ (typically, unit vectors) are assigned to each of the R labels. With this assignment,

$$f(A)(t) = \int_{-\infty}^{\infty} K(t - \tau) \times \sum_{j=1}^{M(A)} \vec{v}_{a(j)} \delta(\tau - t_j^A) d\tau \quad (9)$$

Thus, the j th event, a spike on neuron $a(j)$ at time t_j , is mapped to a bump (the kernel shape) “pointing” in the direction $\vec{v}_{a(j)}$ that has been

assigned to neuron $a(j)$. The angles between the vectors $\vec{v}_i$ correspond to the extent to which the spike train distance is sensitive to the label associated with each spike. An alternative approach is to define multidimensional kernels that spill over from one neuron's spike train to another's (Tezuka 2014, 2018).

In the above examples, the embeddings are linear, and, moreover, time reversal (formally, replacing each t_j with $T - t_{M(A)+1-j}$) has no effect on the resulting distances. Neither of these properties is needed for an embedding to yield a metric; in fact, there are biological motivations to consider distances that derive from embeddings but lack these properties. For example, as a consequence of synaptic facilitation and depression (Sen et al. 1996), the effect of a spike on a post-synaptic neuron depends on how much time has elapsed since the previous spike. This dependence can be incorporated into an embedding function (Brasselet et al. 2011a; Houghton 2009), conferring on it both nonlinearities and time-reversal asymmetries.

Spike train distances based on an embedding can also emphasize their discrete aspect. Specifically, a spike train can be discretized into “bins” of width ΔT (typically chosen to be short enough so that no bin contains more than two spikes) and then regarded as a binary sequence. The Hamming distance between two discretized spike trains (i.e., an L^1 distance in a vector space of dimension $T/\Delta T$) is a spike train distance. The main distinction is that in contrast to the kernel-based distances discussed above, spike trains that have spikes in different bins are regarded as equally distant, regardless of whether or not the times of occurrence of the spikes are close.

Embeddings can also be used to construct measures of spike train **similarity** (i.e., measures that decrease as spike trains become more dissimilar), via the normalized inner product

$$\rho(A, B) = \frac{\langle f(A), f(B) \rangle}{\|f(A)\| \|f(B)\|}, \quad (10)$$

where $\langle u, v \rangle$ is the inner product in the vector space V and $\|v\| = \sqrt{\langle v, v \rangle}$ is the corresponding norm. These similarity measures have an exact

correspondence to a spike train distance, as $\cos^{-1}(\rho(A, B))$ is a metric, namely, the geodesic distance between the unit vectors in the direction of $f(A)$ and $f(B)$ on the unit sphere. The Haas and White measure (Haas and White 2002) uses an exponential kernel for the embedding (Eq. 6); the Schreiber measure (Schreiber et al. 2003) uses a Gaussian kernel. Since these measures are normalized for the spike count of the individual spike trains, they are only sensitive to temporal pattern, and a provision needs to be made for the empty spike train.

Cost-Based Spike Train Distances

While distances constructed via vector space embeddings focus on either the continuous or discrete aspects of the topology of spike trains, cost-based distances attempt to combine these two facets.

The prototypical example was introduced by Victor and Purpura, the “spike time” distance (Victor and Purpura 1997). As is the case for the other distances in this class, the key ingredient is a set of elementary transformations between spike trains, each of which is assigned a cost. Once the elementary transformations have been specified, the distance between two spike trains is the minimal total cost required to transform one spike train into another. That is, the distance $D(A, B)$ is defined as

$$D(A, B) = \min \sum_{k=0}^{K-1} c(X_k, X_{k+1}), \quad (11)$$

where $X_0, \dots, X_K$ is a sequence of spike trains with $X_0 = A$ and $X_K = B$ and each successive spike train linked to the next by an elementary transformation of cost $c(X_k, X_{k+1}) = c(X_{k+1}, X_k)$. For the specific case of the spike time distance, the elementary transformations consist of (i) inserting a spike into a spike train, (ii) deleting a spike from a spike train, and (iii) shifting a spike in time. Inserting or deleting a spike is assigned a cost of 1; shifting a spike by an amount of time Δt is assigned a cost $q|\Delta t|$. The parameter q plays the same role as the parameter $1/t_0$ for the kernel-based distances (Eq. 7): as q increases (or as t_0 decreases), the distance becomes progressively more sensitive to fine timing differences. For

$q = 0$, the distance is entirely insensitive to timing differences (so, formally, it is a pseudometric), since spikes can be moved “for free.” In this limit, the distance which is often called the “spike count distance” is simply the difference in spike counts, $D(A, B) = |M(A) - M(B)|$.

The choice of elementary transformations determines the qualitative nature of the distance. A contrasting example of the spike time distance is the “interspike interval” distance (Victor and Purpura 1997), in which the elementary transformations act on interspike intervals, rather than on the spike times themselves. Since changing the length of one interspike interval shifts the time of all successive spikes, two spike trains can be close in terms of the spike interval distance, but not in terms of the spike time distance. Thus, these distances confer different topologies on the space of spike trains: the topology of the spike time distance is equivalent to that of the van Rossum distance (Eq. 6) with a typical kernel, but the topology of the spike interval distance is not. Additionally, the spike time distance is invariant under parallel translation (adding a common spike train to the spike trains being compared, as in Eq. (5)), while the spike interval distance is not. Cost-based distances are typically non-Euclidean (Aronov and Victor 2004; Dubbs et al. 2010).

Cost-based distances are also applicable to the multineuron setting (Aronov et al. 2003). For the spike time distance, a straightforward approach is to include an elementary transformation that assigns a cost to changing the neuronal label associated with a spike. Parametric variation of this cost changes the character of the distance from one that is sensitive to overall population activity (low cost to change the label) to one that is sensitive to cross-population patterns (high cost to change the label).

For cost-based distances, the overall distance and the costs associated with elementary transformations can be interpreted in terms of a generative model for spike trains (Dauwels et al. 2009). Cost-based distances can also be formulated in terms of “alignments” between spikes, rather than transformations (Dubbs et al. 2010).

The above constructions can be generalized in many ways. To name a few, normalization by spike count can be applied; the costs of each transformation (Victor et al. 2007) or alignment (Dubbs et al. 2010) can be transformed by a power law prior to summation; elementary transformations sensitive to burst structure can be added (Victor and Purpura 1997); and different kinds of elementary transformations can be combined.

Timescale-Independent Spike Train Distances

Complementary to the timescale-dependent approaches, in recent years spike train distances have been proposed which are timescale and thus parameter free since they always adapt to the local firing rate. While not allowing the functional characterization and precision analysis described above, single-valued methods give an objective and comparable estimate of neuronal variability (Chicharro et al. 2011). Measures in this group include the ISI-distance (Kreuz et al. 2007), the SPIKE-distance (Kreuz et al. 2013), and the SPIKE-synchronization (Kreuz et al. 2015).

ISI-Distance and SPIKE-Distance

The ISI-distance D_I and the SPIKE-distance D_S rely on instantaneous values in the sense that in a first step the sequences of discrete spike times are transformed into piecewise-continuous dissimilarity profiles $I(t)$ and $S(t)$. For the ISI-distance (Kreuz et al. 2007), the dissimilarity profile is derived from the interspike intervals, while in the case of the SPIKE-distance (Kreuz et al. 2013), it is extracted from differences between the spike times of the two spike trains. Both distances are then defined as the temporal average of the respective dissimilarity profile, e.g., for the SPIKE-distance

$$D_S = \frac{1}{T} \int_{t=0}^T S(t) dt. \quad (12)$$

The two dissimilarity profiles rely on three piecewise constant quantities which for each neuron ($X = A$ or $X = B$ below) are assigned to every time instant between 0 and T . These are the time of the preceding spike

$$t_P^X(t) = \max(t_i^X | t_i^X \leq t), \quad (13)$$

the time of the following spike

$$t_F^X(t) = \min(t_i^X | t_i^X > t), \quad (14)$$

and the interspike interval

$$z_{ISI}^X(t) = t_F^X(t) - t_P^X(t). \quad (15)$$

The ambiguity regarding the definition of the very first and the very last interspike interval is resolved by means of auxiliary spikes (Kreuz et al. 2015).

ISI-Distance The ISI-distance (Kreuz et al. 2007) is a time-resolved, symmetric, and timescale-adaptive measure of the relative firing rate pattern. It is defined as the normalized ratio between the instantaneous interspike intervals $z_{ISI}^A(t)$ and $z_{ISI}^B(t)$ (Fig. 1a):

$$I(t) = \frac{z_{ISI}^A(t) - z_{ISI}^B(t)}{\max(z_{ISI}^A(t), z_{ISI}^B(t))}. \quad (16)$$

This quantity is 0 when the ISIs in the two spike trains are equal and approaches -1 and 1 , respectively, if the first or the second spike train is much faster than the other. Since both directions of deviation from identical ISIs are equally important, the ISI-distance is calculated by temporal averaging over the absolute values $|I(t)|$ in Eq. (12).

SPIKE-Distance The ISI-distance relies on the relative length of simultaneous interspike intervals and is thus capable to quantify similarities in the neurons' firing rate profiles. However, it is not optimally suited to track synchrony that is mediated by spike timing. This issue is addressed by the SPIKE-distance (Kreuz et al. 2013) which combines the properties of the ISI-distance with a specific focus on spike timing.

The dissimilarity profile of the SPIKE-distance is based on differences between the spike times in

the two spike trains. It is calculated in two steps: first, for each spike, the distance to the nearest spike in the other spike train is calculated. Then, for each time instant, the relevant spike time differences are selected, weighted, and normalized. Here "relevant" means "local," i.e., each time instant is uniquely surrounded by four corner spikes: the preceding spike of the first spike train t_P^A , the following spike of the first spike train t_F^A , the preceding spike of the second spike train t_P^B , and, finally, the following spike of the second spike train t_F^B (Fig. 1b). Each of these corner spikes can be identified with a spike time difference, for example, for the previous spike of the first spike train

$$\Delta t_P^A = \min_k (|t_P^A - t_k^B|) \quad (17)$$

and analogously for t_F^A , t_P^B , and t_F^B .

For each spike train separately, a locally weighted average is employed. The weighting factors ensure that the differences for the closer spike dominate: the weighting factors depend on

$$z_P^A(t) = t - t_P^A(t) \quad (18)$$

and

$$z_F^A(t) = t_F^A(t) - t, \quad (19)$$

the intervals to the previous and the following spikes for each neuron. The local weighting for the spike time differences of the first spike train reads

$$S_A(t) = \frac{\Delta t_P^A(t) z_F^A(t) + \Delta t_F^A(t) z_P^A(t)}{z_{ISI}^A(t)}. \quad (20)$$

For the second spike train, $S_B(t)$ is obtained analogously.

Averaging over the two spike train contributions and normalizing by the mean interspike interval yield

$$S'(t) = \frac{S_A(t) + S_B(t)}{2 \langle z_{ISI}^X(t) \rangle_{X=A,B}}, \quad (21)$$

Spike Train Distance, Fig. 1 Schematic of the three timescale-independent measures. (a) The variables that define the ISI-distance. The instantaneous interspike intervals are used as estimates of the local firing rate. (b) Additional variables employed in the definition of the SPIKE-distance, which is based on spike time differences. (c) Coincidence criterion for SPIKE-synchronization. The coincidence window of each spike is derived from its two surrounding interspike intervals. The two spikes on the left side are considered coincident since both lie in each other's coincidence windows, while on the right, there is no

coincidence since the spike from the second spike train is outside of the coincidence window from the spike of the first spike train. The quantity $\tau_{ij}^{A,B}$ in the text (Eq. 24) is defined as $\tau_{ij}^{A,B} = \min(\tau_i^A, \tau_j^B)$. (Modified with permission from Fig. 1 of Satuvuori E, Malvestio I, Kreuz T: Measures of spike train synchrony and directionality In: Neuro-Math, Mathematical and Computational Neuroscience: Cell, Network and Data analysis (Springer INdAM series, 2018))

where $\langle z_{ISI}^X(t) \rangle_{X=A,B}$ is the average of the local ISIs of spike trains A and B .

This quantity weights the spike time differences for each spike train according to the relative distance of the corner spike from the time instant under investigation. Averaging over this dissimilarity profile $S'(t)$ according to Eq. (12) yields the rate-independent SPIKE-distance (RI-SPIKE-distance) D_S^{RI} (Satuvuori et al. 2017), which

completely disregards any rate differences between the two spike train and thus focuses purely on spike timing information.

In order to also account for differences in firing rate, in a last step, the two contributions from the two spike trains are locally weighted by their instantaneous interspike intervals. This leads to the dissimilarity profile of the SPIKE-distance

$$S(t) = \frac{S_A(t)z_{ISI}^B(t) + S_B(t)z_{ISI}^A(t)}{2\langle z_{ISI}^X(t) \rangle_{X=A,B}^2} \quad (22)$$

which is thus sensitive to both spike rate and spike timing (Satuvuori and Kreuz 2018).

The dissimilarity profiles of both the ISI-distance and the SPIKE-distance and thus both distances are bounded in the interval $[0, 1]$. For the ISI-distance, the minimum value 0 is obtained for any periodic spike trains with the same period. Thus the ISI-distance is a pseudometric, in which all spike trains with a certain constant interspike interval but overall time shifts form the equivalence classes (Mulansky et al. 2015). On the other hand, for the SPIKE-distance, the value 0 is indeed obtained only for perfectly identical spike trains, but it is possible to construct examples that violate the triangle equality (Mulansky et al. 2015), so the SPIKE-distance is not a metric.

For both distances there exists a straightforward extension to estimate the time-resolved level of dissimilarity within a group of spike trains (Kreuz et al. 2009, 2013). It is the straightforward average over all pairs of spike trains, but in these cases, the averaging can be performed locally, e.g., for the SPIKE-distance:

$$S^a(t) = \frac{1}{M(M-1)/2} \sum_{n=1}^{M-1} \sum_{m=n+1}^M S^{mn}(t). \quad (23)$$

SPIKE-Synchronization

SPIKE-synchronization (Kreuz et al. 2015) acts as coincidence detectors and quantifies the level of synchrony from the number of quasi-simultaneous appearances of spikes. It is a measure of similarity, i.e., for identical spike trains, it yields not its minimum value 0 but its maximum value 1.

The calculation consists of two steps, coincidence detection and a combination of normalization and windowing. The first step builds on the same bivariate and adaptive coincidence detection that was used for event synchronization (Quiroga et al. 2002). The temporal resolution can be adjusted with a coincidence window of fixed size τ , but in the parameter- and timescale-free main variant, the maximum time lag $\tau_{ij}^{A,B}$ up to

which two spikes t_i^A and t_j^B are considered to be synchronous is adapted to the local spike rates according to:

$$\tau_{ij}^{A,B} = \frac{1}{2} \min \left[t_{i+1}^A - t_i^A, t_i^A - t_{i-1}^A, t_{j+1}^B - t_j^B, t_j^B - t_{j-1}^B \right]. \quad (24)$$

The coincidence criterion can be quantified by means of a coincidence indicator

$$C_i^A = \begin{cases} 1 & \text{if } \min_j (|t_i^A - t_j^B|) < \tau_{ij}^{A,B} \\ 0 & \text{otherwise} \end{cases} \quad (25)$$

(and analogously for C_j^B), which assigns to each spike either a one or a zero depending on whether it is part of a coincidence or not (Fig. 1c). Here the minimum function already takes into account that a spike can at most be coincident with one spike in the other spike train. If a spike is exactly in between two spikes from the other spike train, this is not considered a coincidence.

The extension to the case of one group of more than two spike trains is straightforward. After performing bivariate coincidence detection for every pair of spike trains, for each spike of every spike train, a normalized coincidence counter

$$C_i^A = \frac{1}{M-1} \sum_{X \neq A} C_i^{A,X} \quad (26)$$

is obtained by averaging over all $M-1$ bivariate coincidence indicators involving the spike train A . This way for both the bivariate and the multivariate case, we have defined a coincidence counter for each individual spike in every spike train. In order to obtain one combined similarity profile, we pool the spikes of all the spike trains as well as their coincidence counters by introducing one overall spike index j . In case there exist exact matches (perfectly coincident spikes), j counts over all of these spikes. From this discrete set of coincidence counters C_j , the SPIKE-synchronization profile $C(t_j)$ is obtained via $C(t_j) = C(j)$. Finally, SPIKE-synchronization is defined as the average value of this profile

$$S_C = \frac{1}{M_p} \sum_{j=1}^{M_p} C(t_j) \quad (27)$$

with $M_p = \sum_X M(X)$ denoting the total number of spikes in the pooled spike train.

The interpretation is very intuitive: SPIKE-synchronization quantifies the overall fraction of coincidences. It is zero if and only if the spike trains do not contain any coincidences and reaches one if and only if each spike in every spike train has one matching spike in all the other spike trains.

SPIKE-synchronization is complementary to the distances described above. It is a measure of spike matching based on a binary coincidence criterion. If converted from a measure of similarity into a measure of distance (by considering $1 - S_C$), it would remain symmetric, but it would fail to be a metric. This is because of the binariness of the coincidence criterion: there are nonidentical spike trains that would have a distance of zero (violating Eq. (1)), and it is possible to construct violations of the triangle inequality (Eq. 3) (Mulansky et al. 2015). SPIKE-synchronization is complemented by SPIKE-order and spike train order (Kreuz et al. 2017), two indicators that allow to sort spike trains from leader to follower and to quantify the consistency of the temporal leader-follower relationships for both the original and the optimized sorting.

All three of these timescale-independent approaches (the ISI-distance, the SPIKE-distance, and the SPIKE-synchronization) have recently been adapted for data containing multiple timescales by adding a notion of the relative importance of local differences compared to the global timescales (Satuvuori et al. 2017).

Other Timescale-Independent Measures

The modulus- and the max-metric (Rusu and Florian 2014) form another family of metrics which is timescale free as well and can also be turned into a time-resolved profile. Both measures are more sensitive to large-scale temporal structure and less sensitive to spike counts and to fine structure within bursts. The most recent proposal

in this group is spike-contrast, a further timescale-independent and multivariate measure of spike train synchrony (Ciba et al. 2018). It mostly yields very similar results to the SPIKE-distance; however, it is complementary since it does not provide a time-resolved dissimilarity profile but instead a synchrony curve as a function of bin size (one of several parameters).

Other Types of Spike Train Distances

There are several useful spike train distances that do not fall into these major categories. The family of metrics proposed in (Wu and Srivastava 2011) resembles an embedding-based metric in that the spike trains are mapped to functions using a kernel; however, these metrics also allow for time to be warped for one spike train relative to the other to bring them into better alignment. In a manner which is reminiscent of a cost-based metric, this warping is associated with a penalty. This metric facilitates the calculation of a “mean spike train,” something that can also be calculated using an embedding-based metric (Julienne and Houghton 2013).

The Hunter-Milton measure compares spike times in one train with the nearest spike times in the other (Hunter and Milton 2003). A choice of scale parameter is required. Lyttle and Fellous have proposed metrics to specifically assess the similarity of spike trains with either common silent periods or bursts (Lyttle and Fellous 2011). Both metrics can be adapted to the dataset by means of several parameters. Finally, the “coincidence factor,” while not a distance, has also been used to compare discretized spike trains based on a normalized count of coincidences (Jolivet et al. 2008; Kistler et al. 1997).

Applications: Analytical Methods

Spike train distances are the starting point for many analysis and modeling strategies. The distinctive feature of this starting point (i.e., considering spike trains to be event sequences, vs. considering them to be vectors) is that it allows for a much more flexible kind of geometry and focuses on intrinsic relations between spike trains, rather than a coordinate system for them. As we

describe below, this enables a variety of approaches to exploratory data analysis, neural coding, and model testing. We first survey these approaches according to the type of analysis and then describe some examples of these applications in neuroscience and behavior. For earlier reviews, see Houghton and Victor (2011), Victor (2005), and Victor and Purpura (2010).

Dimension Reduction

A main challenge in analyzing neural data is its high dimensionality. Thus, as a first step in exploratory analysis or data visualization, it is often helpful to construct a low-dimensional representation of a dataset that preserves key aspects of its structure. From the spike train distance viewpoint, the central goal is to preserve similarity; thus, the crucial requirement in dimensional reduction is to preserve the metric.

The classical approach to accomplishing this is standard multidimensional scaling (Kruskal and Wish 1978), which can be directly applied to spike metrics. Multidimensional scaling is algebraically related to principal components analysis, but in multidimensional scaling, there is no need to identify coordinates or to conceptualize the spike trains as points in a vector space. When applied to a cost-based distance, multidimensional scaling approach often leads to a representation of the neural responses that recapitulates the geometry of the domain being represented (e.g., spatial phase (Aronov et al. 2003) or sound location (Victor and Purpura 1997)).

The global geometry of cost-based distances is typically non-Euclidean (Aronov and Victor 2004). As a consequence, standard multidimensional scaling can at best approximate these (and perhaps other) spike train distances. One approach to this problem is to apply multidimensional scaling to a monotonic function of the distance (such as d^p for $0 < p < 1$), rather than the raw distances themselves. For a sufficiently small but data-dependent p , these derived distances can be exactly embedded into a Euclidean space. An alternative approach is to seek an embedding that focuses on local geometry: the isomap (Tenenbaum et al. 2000) or local linear

embedding (Roweis and Saul 2000) approaches can be used to expand a locally Euclidean representation to a non-Euclidean manifold. The t-distributed stochastic neighbor embedding (t-SNE) is another such nonlinear dimensional reduction approach, which is particularly suitable for sampled data and also focuses on local geometry. Specifically, combining spike train metrics with t-SNE (van der Maaten and Hinton 2008) has been found to be effective for single-neuron and multineuronal datasets (Vargas-Irwin et al. 2015), as well as for nonneural data – bat biosonar, an acoustic emission that can be considered as a sequence of pulses (Accomando et al. 2018).

Information-Theoretic Analysis

Spike train distances are also the starting point for information-theoretic analyses of neural coding. For example, they can be used as a way to estimate the **mutual information** between a set of stimuli and a set of responses, by determining the extent to which neural responses to a set of stimuli form reliable clusters. The dependence of this estimate on the kind of spike train distance used (e.g., one that is sensitive to spike times, vs. spike intervals, or the degree of temporal precision of the distance) points to the features of the neural response that carries the information (Satuvuori and Kreuz 2018; Victor and Purpura 1997). Spike train distances can also be combined with the Kozachenko-Leonenko estimator (Kozachenko and Leonenko 1987) to provide estimates of mutual information, without the need for explicit clustering (Houghton 2015; Houghton 2019; Shapira and Nelken 2013). It is important to note, however, that these approaches typically yield underestimates of mutual information, since they focus on a single timescale and use a very limited number of parameters to describe the possible relationships between spike trains (Lopes-dos-Santos et al. 2015).

Model Evaluation

Spike train distances provide a way to measure the quality of a neural model, by determining the distance between experimentally observed spike trains and models of them (Kameneva et al. 2015). Extending this idea, a spike time distance can also

be used as a cost function to be minimized by adjusting model parameters (Lynch and Houghton 2015) or as a cost function to drive learning algorithms that shape artificial networks to process temporal patterns (Florian 2012). They can also provide a way to quantify whether a model accounts for neuronal variability, by determining the distances between members of a set of spike trains that represent samples of spontaneous activity or samples of responses to the same stimulus.

Applications to Neuroscience

As spike train metrics are metrics on sequences of events, they can be applied to any problem where the data are sets of event sequences. However, they are primarily designed to express the metric structure of spike trains that is functionally or mechanistically relevant and are most often applied to the analysis of electrophysiological data.

One frequent application is as a tool for quantifying how information is coded in spike trains. In describing the different spike train metrics, it has been noted that they often have a parameter interpolating between a spike count pseudometric and metrics in which the precise timing of individual spikes is very significant. In the case of the embedding metrics, this parameter is the width of the kernel used in the embedding, for example, if the kernel is given by Eq. (7), it is t_0 ; in the case of the cost-based metric, it is q , the cost of moving a spike (see discussion following Eq. (11)). This parameter can be fitted to stimulus-evoked spike train data by choosing the value where the metric-based clustering best matches clustering according to stimulus. This gives an indication of the temporal scale relevant to the coding of information about the stimulus in the spike trains. This approach was used, for example, in analyzing visual responses in V1, V2, and V3 in monkey in Victor and Purpura (1996) and in analyzing auditory responses in zebra finch in Narayan et al. (2006). A related approach is used in Brasselet et al. (2009, 2011b) where a metric analysis combined with a novel definition of mutual information is used to argue for the primacy of the latency of first spike in encoding tactile information in human microneurography data.

In multineuronal spike train metrics, there is often a parameter which specifies how significant the individual neurons are in coding; this parameter interpolates between a population code where the identity of the neuron firing a spike has no effect on the distance and a “labeled line code” where the spike train distance between a pair of multineuron spike trains is effectively the sum of the distances between the individual pairs of spike trains for individual neurons. This was used, for example, in Clemens et al. (2011) to analyze the degree of population coding of auditory information in grasshoppers.

These applications all compare responses by the same neuron, or neurons, across different stimuli. Another application of spike train metrics is the detection of cell assemblies; this involves comparing the spiking responses of different neurons to the same stimulus (Humphries 2011, 2017): roughly, a network is formed whose nodes correspond to neurons and the links to a measure of similarity derived from a spike train metric; assemblies are then identified using community detection algorithms. This approach has been applied to CA3 in hippocampus (Li et al. 2010), to reaching tasks in monkey (Newman et al. 2011), and similar ideas can be applied to recordings of activity in the retina (Cutts and Eglén 2014). In Kreuz et al. (2013), the SPIKE-distance is used to study synchrony between recording sites in data recorded from epilepsy patients. It is demonstrated that during ictal periods, there is an elevated level of neuronal synchrony in the hemisphere containing the seizure focus.

It is important to note that the spike metric framework, by itself, is not a statistical one – a spike metric yields a number that indicates the distance between two specific spike train examples, and not a way of assessing whether this difference is statistically significant. Any assessment of statistical significance requires either a model for spike train variability or experimental assessment of this variability, which is independent of the choice of the metric. With a model of variability or a data-driven assessment of it, standard statistical techniques (either parametric or nonparametric) can be applied.

Computation of Spike Train Distances

Computation of distances based on embeddings is straightforward, as the essential steps are convolution and pairwise multiplication. Houghton and Kreuz (2012) introduced a markage trick which reduces the computational cost for the regular van Rossum metric between two spike trains of similar length, $M(A) \sim M(B)$, to order $M = M(A) + M(B)$ from order M^2 . The same markage trick can also be used for the multineuron extension.

For cost-based distances, dynamic programming algorithms modeled after alignment algorithms for genetic sequences (Needleman and Wunsch 1970; Sellers 1974) provide an efficient way to identify the minimal-cost sequence of transformations in the single-neuron setting and for settings with a small number of neurons. The number of computations is approximately $O(M^2)$ for unlabeled spike trains containing M events and $O(M^{R+1})$ when R neurons (labels) are present. These algorithms extend to enable simultaneous computation of distances for all values of its parameters (cost to move a spike, cost to change a label) (Victor et al. 2007). For the single-neuron scenario and single values of the cost parameter, a graph-theoretic approach based on the “Hungarian” algorithm may provide improved performance (Dubbs et al. 2010). For five or more neurons, an incremental matching algorithm (Diez et al. 2012) is the most efficient approach currently available; the computational complexity (specifically, the number of computations required) scales approximately as M^6 , independent of the number of neurons.

Finally, the calculation of the time-resolved and timescale-independent spike train distances is very straightforward since it involves only simple arithmetic. Computational complexity for the ISI-distance and the SPIKE-distance is $O(M)$; for SPIKE-synchronization, it is $O(M^2)$.

A comprehensive compilation of links to code to calculate spike train distances can be found at <http://wwwold.fi.isc.cnr.it/users/thomas.kreuz/sourcecode.html>. Additionally, software for the cost-based distances may be found at <http://www-users.med.cornell.edu/~jdvicto/pubalgor.html>, <http://www.csse.monash.edu.au/~lloyd/tildeAlgDS/Dynamic/Edit/>, and in the Spike Train Analysis

Toolkit, at <http://neuroanalysis.org/>. The latter site also includes modules for information-theoretic calculations based on these distances.

Definition

The spike-triggered average (STA) is a measure to relate a continuous signal and a simultaneously recorded spike train. It represents the average signal taken at the times of spike occurrences and with proper normalization is equivalent to the cross-correlation between the continuous signal and the spike train.

Detailed Description

The STA is widely used to study the temporal relationship between a spike train and a simultaneously recorded continuous signal, such as the local field potential (Eckhorn et al. 1988; Gray and Singer 1989; Murthy and Fetz 1996; Fries et al. 2001; Okun et al. 2010; Denker et al. 2011), membrane potential (Matsumura et al. 1996; Lampl et al. 1999; Poulet and Petersen 2008), synaptic conductance (under dynamic clamp, Gauck and Jaeger 2000) and electromyogram (McKiernan et al. 1998). Even non-physiological signals, such as electric stimulation to a single neuron (Mainen and Sejnowski 1995) or visual (Ringach and Shapley 2004) and auditory (Eggermont et al. 1983) stimulation, have been related to a spike train via the STA. In such cases the STA is commonly referred to as reverse correlation.

Here we introduce the STA in relation to the local field potential (LFP). The LFP signal is obtained as a low-frequency component, typically below approximately 100 Hz, of extracellular recordings of neuronal electric activity. Its physiological origin is the transmembrane current of neurons in the vicinity of the recording electrode (Mitzdorf 1985; Nunez and Srinivasan 2006). Theoretical considerations and experimental observations have elucidated that the strongest contribution to the LFP is from the currents caused by postsynaptic potentials, while the influence of action potentials on the LFP is weak (Mitzdorf 1985; Logothetis 2003; Buzsaki et al. 2012). Therefore, the LFP predominantly reflects the synaptic inputs to the local neuronal circuit around the tip of the recording electrode (including the recurrent inputs due to internal processing of the circuit) (Logothetis 2003). This view is further strengthened by the observation that temporal modulations of the (intracellularly recorded) somatic membrane potential of a single cell, which represent net synaptic input to the cell, are tightly correlated with modulations of the (extracellularly recorded) LFP in the vicinity of that same cell (Poulet and Petersen 2008; Okun et al. 2010). Given that spikes are the output of single

neurons, the relationship between simultaneously recorded spikes and LFPs could be interpreted as reflecting the input–output relation of the local brain area [cross-ref: Local Field Potential, Relationship to Unit Activity].

It has been shown in various species and various cortical/subcortical brain regions that LFPs exhibit distinct oscillations in a wide range of frequencies (Buzsaki 2006). Previous studies have identified modulations of these oscillatory activities as reflecting changes in the functional states of perceptual, cognitive, and motor processes in the brain. An important question about the spike-LFP relation would therefore be whether, and if so how, temporal modulations of spiking activity are related to LFP oscillations or, more concretely, how the timings of spike occurrences correlate with the phase of LFP oscillations.

The spike-triggered average (STA) is a commonly used measure for assessing the temporal relation between a spike train and an LFP signal. Assume simultaneous recordings of a spike train, represented as time points t_i ($1 \leq i \leq N$; N , total number of spikes) of spike occurrences, and an LFP signal, represented by $X(t)$, where t is time. For simplicity, also assume that the recording time is sufficiently long. The STA is defined as

$$STA(\tau) = \frac{1}{N} \sum_{i=1}^N X(t_i + \tau), \quad (1)$$

i.e., the average value of $X(t)$ at a given time lag τ in relation to the spike time t_i . This is equivalent to the cross-correlation (with normalization by the number of spikes) between the LFP signal and the spike train:

$$STA(\tau) = \frac{1}{N} \int_{-\infty}^{\infty} X(t + \tau) Y(t) dt,$$

with $Y(t) = \sum_{i=1}^N \delta(t - t_i)$ representing the spike train as a sum of Dirac delta functions $\delta(\cdot)$. Typically the STA is computed for a range of lags τ around the spike times, so that the waveform of the STA as a function of the lag illustrates the average modulation of the LFP around the

occurrences of spikes. The STA obtained in this manner is widely used as a measure of the temporal locking of spikes to oscillatory LFP modulations (Eckhorn et al. 1988; Gray and Singer 1989; Murthy and Fetz 1996; Fries et al. 2001; Okun et al. 2010; Denker et al. 2011).

When spikes occur preferentially at a specific phase of LFP oscillations, the summation in the right-hand side of Eq. 1 accumulates LFP values at similar phases of the oscillation for each lag τ , resulting in the STA having an oscillatory waveform with the preferred phase represented at $\tau = 0$. Thus, the degree of temporal spike-to-LFP locking can be evaluated by the strength of oscillatory modulations of the STA, i.e., the greater the modulation, the stronger the locking. A caveat is, however, that the strength of modulation depends not only on the degree of locking but also on the amplitudes of the oscillatory components of the LFP signal. One way to quantify the degree of locking in spite of this amplitude dependence is to estimate the significance of the oscillatory modulation in the obtained STA by use of a bootstrap method. Commonly used methods include trial shuffling, spike randomization, and spike dithering [cross-ref: Surrogate Data for Evaluation of Spike Correlation]. A proper use of bootstrap significance tests also enables rejection of artificial locking due to non-stationarities in the firing rate of the spike train (Grün 2009; Louis et al. 2010).

The oscillatory power of LFP signals typically shows a strong dependence on frequency. Therefore, the amplitude dependence causes another concern when the LFP signal contains oscillatory components at multiple frequencies and one wishes to compare the strengths of the spike-to-LFP locking at different frequencies. To normalize for the difference in power at different frequencies, it is possible to move from the time domain to the frequency domain. Spike-field coherence (SFC) is a measure derived from the STA through such normalization. It is defined as

$$SFC(f) = |\tilde{STA}(f)|^2 / |\tilde{X}(f)|^2,$$

where

$$\begin{aligned} \tilde{STA}(f) &= \int_{-\infty}^{\infty} STA(\tau) e^{-2\pi i f \tau} d\tau, \tilde{X}(f) \\ &= \int_{-\infty}^{\infty} X(t) e^{-2\pi i f t} dt, \end{aligned}$$

i.e., the power spectrum of the STA normalized by the power spectrum of the LFP signal used to compute the STA (Fries et al. 2002). For each frequency, f , the SFC takes on a value between 0 and 1, which corresponds to independence and to perfect locking, respectively, between the spike train and the corresponding spectral component of the LFP. Owing to the normalization by the LFP power, SFC serves as a proper measure for comparison of the degree of spike-to-LFP locking at different frequencies. Studies have shown that the modulation of SFC is related to various aspects of brain function such as sensory processing (Womelsdorf et al. 2006), attention (Chalk et al. 2010), working memory (Pesaran et al. 2002), and decision making (Pesaran et al. 2008).

Definition

When stimulated with a constant stimulus, many neurons initially respond with a high spike

Spike-Frequency Adaptation, Fig. 1 Phenomenon spike-frequency adaptation. (a) Spike train (vertical strokes at the top) of an adapting neuron evoked by the onset of a constant stimulus (green bar at the bottom, $I = 15$ nS). The spike frequency drops from an initially high onset rate, f_0 , in an approximately exponential way down to a lower steady-state rate, f_∞ . (b) Repeating the experiment shown in (a) for various stimulus intensities

I (here an injected current) results in the onset f - I curve $f_0(I)$ and the steady-state f - I curve $f_\infty(I)$. Shown are simulations of a single-compartment conductance-based model with an M-type current (the Ermentrout model; Ermentrout 1998; Benda et al. 2010; with $\dot{g}_{Ca} = 0$, $\dot{g}_{AHP} = 0$, and $\dot{g}_M = 8 \mu\text{S}/\text{cm}^2$, the input current is scaled such that 1 nA equals $1 \mu\text{A}/\text{cm}^2$)

frequency that then decays down to a lower steady-state frequency (Fig. 1a). This dynamics of the spike-frequency response is referred to as “spike-frequency adaptation”. Spike-frequency adaptation is a process that is slower than the dynamics of action-potential generation. Spike-frequency adaptation by this definition is an aspect of the neuron’s super-threshold firing regime, although the mechanisms causing spike-frequency adaptation could also be at work in the neuron’s subthreshold regime.

Detailed Description

In the context of spike-frequency adaptation, spike frequency is often measured as the instantaneous rate, i.e., the averaged reciprocal interspike intervals at each time. This measures the inverse period of super-threshold firing. In contrast, the PSTH (peristimulus time histogram (► [Estimation of Neuronal Firing Rate](#))) estimates the probability of a spike at a given time and therefore is also sensitive to variability of the response caused by intrinsic or external noise sources.

Important characteristics of a neuron with spike-frequency adaptation are its f - I curves (spike frequency f versus input strength I).

Because of adaptation, a certain input intensity will not evoke a constant spike frequency. Instead, the initial response in spike frequency to the onset of a constant input will result in the so-called “onset f - I curve” (green curve in Fig. 1b). Later during the constant stimuli, the spike frequency reaches a steady state. Drawn as a function of input intensity, this forms the “steady-state f - I curve”, which usually lies below the onset f - I curve, because the spike frequency adapts from the onset down to the steady state (red curve in Fig. 1b). The third type of f - I curves is the “adapted f - I curves” (Benda and Herz 2003). For these the neuron is first adapted to some adaptation input of fixed intensity and then the onset responses to various test inputs are measured (Fig. 2). The adapted response curves indicate how the neuron being in a certain and fixed adaptation state will initially respond to new stimuli. While each neuron has exactly one onset and one steady-state f - I curve, it has for each adaptation stimulus a different adapted f - I curve.

Simple adaptation currents (see below) will shift the neuron’s adapted f - I curves to higher input intensities. Other (less well-understood) mechanisms like presynaptic inhibition may also tilt the adapted f - I curves (Hildebrandt et al. 2011) or distort it in other ways (see also Fig. 5).

Spike-Frequency Adaptation, Fig. 2 Adapted $f-I$ curves. In addition to the onset and the steady-state $f-I$ curves, the adapted $f-I$ curves provide important information about the adaptation properties of a neuron. (a) In order to measure an adapted $f-I$ curve for a specific adaptation state, the neuron is first adapted to its steady-state response $f_\infty(I_0)$ by stimulating it with a constant adapting stimulus I_0 (here 15 nA). Then, a test stimulus I is applied and the onset response $f_0(I, I_0)$ to this stimulus is measured.

In the figure, the responses (red and orange) to two different test stimuli ($I = 20$ nA in green and $I = 10$ nA in dark cyan) are shown. (b) Each adapting stimulus I_0 results in one adapted $f-I$ curve $f_0(I, I_0)$. Shown are adapted $f-I$ curves for $I_0 = 5, 10, 15, 20$ nA. In this example the adaptation process mainly shifts the adapted $f-I$ curves to the right. All curves together characterize the spike-frequency response of an adapting neuron. Same model neuron as in Fig. 1

Spike-frequency adaptation is related to the classification of neurons into phasic, phasic-tonic, or tonic spiking neurons. Tonic spiking neurons are neurons that keep firing in response to a constant stimulus with an almost constant rate. Many neurons that are classified as tonic spiking, however, still show some weak spike-frequency adaptation. On the other hand, phasic spiking neurons only emit one or several spikes to the onset of the stimulus and then cease spiking. If this onset response consists of several spikes with a decreasing spike frequency, then the phasic response is probably caused by strong spike-frequency adaptation. With less or only a single spike and no clear decrease in spike frequency, this type of response can be that of a type III neuron (► [Excitability: Types I, II, and III](#)). The intermediate phasic-tonic responses exactly match the definition of spike-frequency adaptation.

Mechanisms

There are many different mechanisms that all cause a neuron to adapt its spike-frequency

response. First, there are adaptation currents – ionic currents (► [Biophysics of Adaptation in a Computational Model of the Leech T Neuron](#)) that act together with the spike-generating currents (“output-driven adaptation”). Second, other mechanisms, such as fatigue of receptor currents, adapt the input a neuron receives (“input-driven adaptation”). And third, there are network effects that also can adapt the neuron’s response in both an input-driven or output-driven way.

Adaptation Currents

There exists a whole zoo of mechanisms based on ionic currents that are all directly or indirectly activated by the action potentials generated by the neuron – the output of the neuron – and have at least one time scale involved that is slower than the dynamics of an action potential.

M-type currents are a simple example (Fig. 3; Brown and Adams 1980). These are voltage-gated potassium currents that are mainly activated at high voltages as they occur during an action potential and that deactivate with a slow time

Spike-Frequency Adaptation, Fig. 3 Dynamics of an adaptation current. (a) The membrane potential V in response to a step input ($I = 15$ nA, indicated by the green bar) simulated with the same model as in Fig. 1. As adaptation progresses the interspike intervals get longer. (b) The gating variable of the M-type current a is

increased by every action potential and decays slowly in between them. This way a slowly builds up during stimulation. (c) The adaptation current, here an M-type current, I_M , gets larger and larger as a increases and inhibits the input. This way it causes the neuron's response to adapt

constant of about 100 ms. If the neuron initially fires with a frequency of say 200 Hz, then the activation of the M-type currents builds up from one action potential to the next, since there is not enough time for the current to completely deactivate between succeeding action potentials. As a potassium current, the activated M-type currents then counteract the input to the neuron and as a consequence the spike frequency is reduced – the neural response adapts.

An important class of adaptation currents are AHP-type currents, calcium-gated potassium currents, that enhance the after hyperpolarization following an action potential (Sah 1996). Here, during each action potential, calcium enters the cell through voltage-gated calcium channels. Depending on the intracellular calcium concentration, the AHP-type currents are activated and as potassium currents inhibit the input to the neuron. Calcium is only slowly removed from the cytosol

and this time scale is then reflected by the resulting spike-frequency adaptation.

Further ionic mechanisms that cause spike-frequency adaptation include sodium-activated potassium channels and slow inactivation of the sodium current (for details see ► [“Biophysics of Adaptation in a Computational Model of the Leech T Neuron”](#)).

Input Adaptation

In receptor neurons the whole transduction process from the physical stimulus to the receptor current can adapt in different ways. These can be mechanisms controlling the sensitivity of the receptor organ, like the pupillary light reflex. Within the receptor neuron itself, the transduction machinery may produce adapting receptor currents due to fatigue (e.g., bleaching of rhodopsin)

or active adaptation to the intensity of the physical stimulus within a second messenger cascade (e.g., in photoreceptors) or by molecular motors (e.g., in mechanical transduction in hair cells (► [Cochlear Inner Hair Cell, Model](#))). All these and many other mechanisms eventually produce an adapting receptor current that then leads to spike-frequency adaptation in the receptor neuron. Gollisch and Herz (2004) demonstrated how to unmask input-driven adaptation from output-driven adaptation in auditory receptor neurons of locusts.

In all other neurons that receive their input through synapses on their dendrite, the input current reaching the site of action-potential generation can also be adapted. The various forms of synaptic dynamics, in particular short-term depression, are potential sources of spike-frequency adaptation. Also various ionic currents on the dendrite (► [Quasi-active Approximation of Nonlinear Dendritic Cables](#)) might potentially adapt the input.

Network Effects

In case the spiking activity of a neuron leads to the activation of recurrent inhibitory synapses, this might cause spike-frequency adaptation in a way quite similar as the adaptation currents (Sutherland et al. 2009). Here, the slow time scale would be introduced by the time scale of the postsynaptic current of the inhibitory synapse, by the delay introduced by wiring, and by the integration dynamics of the neurons participating in this negative feedback loop.

Similar to input-driven adaptation, some forms of feedforward input may also cause spike-frequency adaptation in the target neuron. In its simplest form, the presynaptic neuron already adapts, and thus, the postsynaptic neuron very likely will adapt as well. In addition, the synaptic transmission might adapt through synaptic plasticity (► [Short-Term Plasticity, Biophysical Models](#)) or by presynaptic inhibition, or delayed and slower inhibitory input can adapt the response of the target neuron.

Network and cell-intrinsic adaptation mechanisms shape in specific ways functionally

different response properties of auditory interneurons in locusts (Hildebrandt et al. 2009).

Models of Spike-Frequency Adaptation

There are many ways to model spike-frequency adaptation. In the following overview, we focus on output-driven adaptation, i.e., adaptation currents that are activated by the neuron's output activity (membrane voltage with action potentials). In contrast, input-driven adaptation is activated by the input signal irrespective of the resulting output.

Conductance-Based Models

In conductance-based models like the Hodgkin-Huxley model (► [Short-Term Plasticity, Biophysical Models](#)), any ionic current of a neuron is modeled in detail. This requires exact knowledge of the specific type of adaptation current involved. For example, the M-type current I_M would be modeled as

$$I_M = \dot{g}_M a (V - E_K) \quad (1)$$

$$\tau_a(V) \frac{da}{dt} = a_\infty(V) - a \quad (2)$$

where E_K is the potassium reversal potential, $\dot{g}_M$ is the maximum conductance, and a is the gating variable of this voltage-gated current. $\tau_a(V)$ and $a_\infty(V)$ are the voltage-dependent time constant and activation variable, respectively, that determine the (slow) temporal evolution of the gating variable. $a_\infty(V)$ is a sigmoidal function depending on the membrane potential V that is close to zero at the resting potential and about one during an action potential (Brown and Adams 1980; Benda and Herz 2003).

Integrate-and-Fire Models

As for conductance-based models, any adaptation current can also be simply added to the input of an

integrate-and-fire model. The only difference is that the effect the action potential has on the dynamics of the current has to be modeled explicitly, for example, by increasing a in Eq. 2 by a certain increment whenever there was a spike.

Often, however, a more generalized form of adaptation currents is used in (leaky, quadratic, exponential) integrate-and-fire neurons (Izhikevich 2003; Brette and Gerstner 2005). This has the advantage that the exact nature of the adaptation current in question does not have to be known. First, the electromotoric force $E_K - V$ is often approximated away, so that the gating variable a then becomes the (appropriately scaled) adaptation current A . Second, $a\infty(V)$ is replaced by incrementing A by some appropriate value ΔA whenever an action potential occurs at time t_i . Between the action potentials, A decays exponentially with a fixed adaptation time constant τ_a :

$$I_M \approx A \quad (3)$$

$$\tau_a \frac{dA}{dt} = -A + \Delta A \sum_{i=-\infty}^{\infty} \delta(t - t_i) \quad (4)$$

The adaptation dynamics (4) can be extended by an additional term proportional to V in order to incorporate the fact that some adaptation currents are already activated by subthreshold membrane voltages.

Integrate-and-fire models with a dynamic threshold are another class of adapting neuron models, where the firing threshold is incremented by each action potential and follows a slow dynamics between the action potentials. Although this mechanism also produces spike-frequency adaptation (Liu and Wang 2001), the resulting adapted f - I curves do not only shift to higher inputs, as any adaptation current does, but also reduce their slopes (Benda et al. 2010).

Firing-Rate Models

By simply approximating the neuron's spike generator by its f - I curve $f_0(I)$ and using Kirchhoff's law that ionic currents over the cell's membrane

add up yield the following equation for the spike frequency $f(t)$:

$$f = f_0(I - A) \quad (5)$$

$$\tau_a \frac{dA}{dt} = -A + A_\infty(f) \quad (6)$$

(Benda and Herz 2003). Because the adaptation current acts inhibitory on the input current, it is subtracted from the input. The dynamics for A is the same as for the simplified integrate-and-fire neurons, but it is driven via the term $A_\infty(f)$ by the output spike frequency and not by individual spikes any more. This dependence on the spike frequency arises from averaging over the spike train in time (Wang 1998). This averaging procedure is possible if the spike frequency is higher than the reciprocal adaptation time constant. Only then the adaptation dynamics can be separated from the one of the membrane potential. Choosing $A_\infty(f)$ to be proportional to f often is a reasonable approximation. Then, the only nonlinearity remaining is the neuron's onset f - I curve. By linearizing the onset f - I curve around the current spike frequency, one can easily compute the neuron's filter properties that are introduced by the adaptation process.

Signal Processing

The slow adaptation variable (gating variable of M-type current, intracellular calcium concentration for AHP-type currents, etc.) is a low-pass filtered version of the output spike train (output-driven adaptation, Eqs. 4 or 6) or of the input to the neuron (in the case of input-driven adaptation). Since this low-pass filtered signal is then subtracted from the input current I , this basically (i.e., with linear f - I curves) results in a high-pass filter between the input to the neuron and the resulting output spike frequency. The spike frequency of an adapting neuron thus encodes the high-pass filtered input signal (Fig. 4; Benda and Herz 2003). For example, in electroreceptors, this high-pass filter resulting from adaptation processes enhances the response to fast stimulus

Spike-Frequency Adaptation, Fig. 4 High-pass filter of adapting neurons. Adaptation processes add high-pass filter characteristics to a neuron's transfer function between the input to the neuron (here, e.g., an injected current) and the resulting spike frequency. Shown is the gain, i.e., the amplitude of the modulation of the spike-frequency response divided by the amplitude of the injected current input as a function of the frequency of that input, obtained for the same model neuron as in Fig. 1. As a stimulus a low-pass filtered Gaussian white noise with cutoff frequency at 16 Hz, mean 10 nA, and standard deviation 2 nA was used. The slopes of the steady-state f - I curve (red) at 10 nA and the one of the adapted f - I curve (green) for $I_0 = 10$ nA are plotted for comparison

components in communication signals (Benda et al. 2005).

The gain of the filter at low stimulus frequencies that are below the reciprocal adaptation time constant is given by the slope of the steady-state f - I curve. The gain of stimulus frequencies faster than the reciprocal adaptation time constant is given by the slope of the adapted f - I curves. In the case of purely subtractive adaptation, the latter equals the slope of the onset f - I curve.

It follows that neurons with flat steady-state f - I curves (zero slope) implement perfect intensity invariance (zero gain at low stimulus frequencies), i.e., no matter on what mean intensity a certain input waveform is delivered, the output spike-frequency will always be the same, since the mean intensity is completely filtered out by the adaptation process (Benda and Hennig 2008).

The high-pass filter effect of spike-frequency adaptation considers the linear aspects of spike-frequency adaptation only. At least the steady-state f - I curve is indeed linearized by adaptation

currents (as shown in Ermentrout 1998, and also illustrated in Fig. 1b). In addition, the nonlinear shape of a neuron's f - I curves (e.g., rectification at zero firing rate and saturation) together with the high-pass filter introduces additional aspects. For example, the subtractive shift of the adapted f - I curves to higher input intensities might be accompanied by a reduction in their maximum firing rate and/or by a reduction of their slope (see Fig. 5 for simple examples) and thereby influence the filter properties of a neuron in a nonlinear way.

The various forms of this interplay of adaptation dynamics and the resulting high-pass characteristics with nonlinearities lead to diverse functional consequences. For example, in the auditory system of crickets, the slow calcium dynamics leads to forward masking of weaker stimuli (Sobel and Tank 1994). A collision-detecting neuron in the visual system of locusts responds very selectively to looming stimuli because of spike-frequency adaptation (Peron and Gabbiani 2009).

Adaptation currents can even alter the type of action-potential dynamics (► **Excitability: Types I, II, and III**). A type I neuron where repetitive firing occurs via a saddle-node bifurcation on an invariant cycle can switch into a type II neuron where the resting potential loses stability via a Hopf bifurcation by the activation of an M-type adaptation current (Ermentrout et al. 2001; Prescott et al. 2006).

Multiple Adaptation Time Scales

Usually, spike-frequency adaptation occurs not only on a single but on several time scales. The shortest time scales of spike-frequency adaptation are in the range of 10–100 ms. This at the same time usually also is the strongest adaptation process in the neuron. Additional slower adaptation processes are weaker and have time constants of seconds, 10 s and slower. Adaptation on several time scales could resemble power-law adaptation (Clarke et al. 2013) or logarithmic adaptation (Xu et al. 1996) in contrast to the single adaptation process showing exponential adaptation of the firing rate.

Spike-Frequency Adaptation, Fig. 5 Nonlinearities and adaptation. Simple subtractive adaptation can have unexpected effects when it occurs after a nonlinearity. The examples show two simple scenarios where the firing rate f of a neuron is directly proportional to the input current J , and an adaptation current A acts subtractive on the current, as in Eq. 5: $f = c \cdot (J - A)$, with $c > 0$, and $f = 0$ if $J < A$. The input current, however, depends nonlinearly on some (sensory) input I : $J(I)$. (a) The input nonlinearity is a

sigmoidal function of the sensory input: $J(I) = (1 + \exp.(-(J - 6)/4))^{-1} - 0.2$ ($c = 320$ Hz). This is the case, for example, in auditory or olfactory receptor neurons. Although the adaptation acts subtractive on the input current, the resulting adapted f - I curves appear to be shifted to the right as well as downward. (b) $J(I) = \cos(0.2 I) + 0.2$ ($c = 180$ Hz). This models, for example, an orientation-selective cell in the visual system. Here, the adapted f - I curves appear to be shifted downward

Noise

Adaptation currents are a potential source of ion channel noise. Since these ionic currents are characterized by their slow adaptation dynamics, the resulting channel noise is a colored noise with correlation time given by the adaptation time constant. Such a noise results in positive correlations between successive interspike intervals and in interspike-interval histograms with a sharper peak and heavier tail in comparison to the ones obtained with white noise (Fig. 6d–f; Schwalger et al. 2010).

Output-driven adaptation also interacts with white noise, e.g., generated by ion channel noise from fast spike-generating currents. In this case, adaptation introduces negative serial correlations between successive interspike intervals (Fig. 6a–c; Chacron et al. 2000; Benda et al. 2010) that improve information transmission at low frequencies (Chacron et al. 2001). The interspike-interval statistics of auditory receptor neurons in locusts have been shown to be shaped by both white noise sources and colored noise presumably generated by an adaptation current (Fisch et al. 2012).

Rhythmogenesis in Neural Networks

The slow decrease in firing frequency due to adaptation currents provides delayed negative feedback that can result in the production of oscillations by excitatory neural networks. The population activity of an excitatory neural network can be roughly described by its mean firing rate, which varies according to

$$\tau \frac{df}{dt} = f_0(I) - f \quad (7)$$

(Wilson and Cowan 1972). Here, the firing frequency f is averaged spatially (over the population) and temporally (over the synaptic integration time scale). It is assumed that the neurons fire asynchronously. f_0 is the steady-state firing rate that will be reached with a network integration time constant τ . It is similar to the function f_0 in Eq. 5, but is not strictly the firing rate of one neuron, as it also incorporates information about synaptic dynamics, heterogeneity in the neuron population, etc. Because of the recurrent excitatory connectivity, the input I to the network is given by $I = wf$, where f is

Spike-Frequency Adaptation, Fig. 6 Spike-frequency adaptation and noise. (a–c) Interspike-interval (ISI) histogram (a), return map (b), and ISI correlations (c) for the conductance-based model with an M-type adaptation current (same model as in Fig. 1) driven with white noise (mean $I = 10$ nA, noise strength $D = 1$ nA²/Hz). (d–f)

The same measures for colored noise arising from the stochasticity of the adaptation current. Noise strength was scaled to result in the same standard deviation of the ISIs ($D = 30$ nA²/Hz). Note the more peaked shape of the ISI distribution as well as the positive ISI correlations

the output firing rate of the network, and w is a connectivity parameter akin to synaptic weight or the number of connections per neuron. If neurons are adapting, the effective input becomes $I = wf - A$, where A is the average adaptation current in the population. This description is valid as long as adaptation is much slower than network integration ($\tau_a > \tau$).

The population firing rate equilibrates to

$$f = f_0(wf - A) \quad (8)$$

and A varies according to Eq. 6. Note that Eq. 8 can have two stable solutions over a range of A values. This bistability, due to the fast positive feedback provided by excitatory connections, together with the slow A dynamics produce relaxation oscillations as illustrated in Fig. 7 (Tabak et al. 2000; van Vreeswijk and Hansel 2001; Giugliano et al. 2004; Gigante et al. 2007).

Note that the exact dependence of adaptation on frequency (here given by Eq. 6 and represented as the blue curve in Fig. 7b) may affect the type of bifurcation that occurs between a silent and an oscillatory network as a source of excitation is

increased (Nesse et al. 2008), but it does not change the fundamental mechanism of the oscillations. So the excitatory network can oscillate whether adaptation is input- or output-driven (Nesse et al. 2008). Synaptic adaptation (often called short-term synaptic depression (► [Synaptic Dynamics: Overview](#))) also produces oscillations in excitatory networks, through the same mechanism as the intrinsic adaptation mechanisms described here (Tabak et al. 2000; Tsodyks et al. 2000; Wiedman and Luthi 2003). Note, however, that the two types of adaptation (intrinsic or synaptic) can be distinguished in models (even in firing rate models) as well as in experiments based on the models' predictions (Tabak et al. 2000, 2010; Wiedman and Luthi 2003). Thus, it is important to pay careful attention to what adaptation model is most appropriate in a particular modeling context.

In addition to its rhythmogenic properties in excitatory networks, activity-dependent adaptation facilitates network-based oscillations due to the interaction of excitatory and inhibitory populations (Augustin et al. 2013). The rhythmogenic mechanism based on excitatory

Spike-Frequency Adaptation, Fig. 7 Oscillatory activity in an excitatory network with adaptation. (a) Time courses of f , the average firing rate (black), and A , the average adaptation current (blue) in the population. During an episode of activity ($f \simeq 1$), A is increasing, until activity drops to $\simeq 0$. During the inter-episode interval, A decreases until the network is excitable enough to start a new high-activity episode. (b) The two time courses from (a) describe a closed trajectory in the (A, f) plane. The red curve is the curve of steady states of f , solutions of Eq. 8 at each value of A . There is an interval of A over which there are two stable steady states for f , one high and one low (and

an intermediate, unstable steady state, dashed). The blue curve represents $A \propto(f)$; when the phase point (A, f) is above this curve, A increases; below this curve A decreases, according to Eq. 6. During an episode of network activity (a), f is high so A increases, moving the trajectory to the right. After the point where the high steady state meets the unstable steady state, the only available steady state is at low f . The trajectory jumps down (b), starting the inter-episode interval (c), during which A decreases. When A is low enough, the lower steady state disappears and the trajectory jumps up (d), beginning a new high-activity episode

connectivity and slow activity-dependent adaptation may underlie various types of network activity such as episodic activity in developing networks (Butts et al. 1999; Tabak et al. 2000), respiratory rhythms (Kosmidis et al. 2004), or slow oscillations between up and down states in cortex (Compte et al. 2003).

Definition

A biophysical model of spike-timing-dependent plasticity (STDP) is one which converts time

intervals, in a given firing pattern of synaptically coupled pre- and postsynaptic neurons, to modifications of the connecting synapse. This class of STDP model is defined by their mathematical representation of specific biophysical quantities, which have been shown to play a role in the intracellular mechanisms underlying synaptic plasticity.

Detailed Description

Within the STDP framework, models of synaptic plasticity are dependent on the precise relative timing of pre- and postsynaptic spikes and, broadly speaking, utilize one, or a combination, of two modelling approaches. The first group of STDP models use phenomenological modelling to empirically describe the relationship between the model inputs (pre- and postsynaptic spike times) and the model output (synaptic weight modification). There is usually little or no attempt to represent the intracellular machinery governing synaptic plasticity in the model. The second group of STDP models use a *biophysical* modelling approach, which means that they include variables that represent specific biophysical species or quantities. The mathematical relationships between the variables in a biophysical model encapsulate our mechanistic understanding of the biochemical and electrophysiological processes that are being modelled. Predictions from biophysical STDP models can therefore offer insight into the mechanisms governing the induction of synaptic plasticity.

Ca²⁺-Based Models of STDP

The critical trigger for synaptic plasticity is a rise in intracellular Ca²⁺ concentration, [Ca²⁺], since synaptic long-term potentiation (LTP) and depression (LTD) are blocked by pharmacological buffering of Ca²⁺ (Malenka and Bear 2004; Graupner and Brunel 2010). The importance of intracellular Ca²⁺ is reflected in the fact that dynamic cytosolic Ca²⁺ levels, acting as intermediate signals for induction of plasticity, are a common feature of most biophysical models of STDP.

Ca²⁺-based biophysical models of STDP must include a description of the changes in [Ca²⁺] due to pre- and postsynaptic spiking. Ca²⁺ sources may depend on the particular synapse to be modelled but most frequently include influx via NMDA receptors (NMDARs), influx via Ca²⁺-permeable AMPA receptors (AMPA), influx via voltage-gated Ca²⁺ channels (VGCCs), or Ca²⁺ release from intracellular stores. Since most modelling efforts are directed towards understanding NMDAR-dependent plasticity, NMDARs are the primary source of Ca²⁺ in the majority of biophysical STDP models. Entry of extracellular Ca²⁺ via postsynaptic membrane ion channels can be dependent on both the postsynaptic membrane potential and the action of neurotransmitters in the synaptic cleft; therefore, biophysical models of STDP often contain descriptions of electrophysiological cell membrane phenomena and AMPAR/NMDAR ligand gating in response to neuron pair spiking. The sophistication of intracellular Ca²⁺ handling within the model can be further increased by the inclusion of Ca²⁺ buffers or plasma membrane ion pumps.

Simplified Intracellular Dynamics

Biophysical STDP models can be categorized according to their method of transposing postsynaptic Ca²⁺ signals into synaptic modifications. In one set of STDP models, simplifications of the forward-connected Ca²⁺-dependent mechanisms underlying synaptic plasticity are used alongside a realistic biophysical treatment of Ca²⁺ dynamics within the postsynaptic neuron. Ca²⁺ signalling networks in these models are reduced to abstract Ca²⁺-signal detection systems or simple algebraic equations, which introduce phenomenological variables relating postsynaptic [Ca²⁺] to synaptic weight changes. These types of STDP models vary in their consideration of the postsynaptic [Ca²⁺] transient, with some using peak magnitude only as their signal (e.g., Shouval et al. 2002; Rackham et al. 2010), while others consider the whole transient (e.g., Rubin et al. 2005). The Ca²⁺ detectors are designed to describe

simplified kinase/phosphatase activity in dephosphorylation/phosphorylation cycles that are critical for synaptic plasticity induction and to capture the essential quality of the Ca^{2+} -control hypothesis, which states that high transient intracellular $[\text{Ca}^{2+}]$ leads to LTP, whereas moderate more prolonged increases in $[\text{Ca}^{2+}]$ result in LTD (Lisman 1989). Examples of models using this approach include Shouval et al. (2002), Abarbanel et al. (2003), Rubin et al. (2005), and Rackham et al. (2010).

The simplest of these models (Shouval et al. 2002, Fig. 1) results in a second LTD

window at large positive STDP time intervals between pre- and postsynaptic spikes, an effect that is not observed in the majority of experimental STDP spike-pair studies. Conflicts with experimental data, such as this, can be remedied by the introduction of further phenomenological variables to “veto” LTD at positive time intervals (Rubin et al. 2005) or by including the stochastic properties of synaptic transmission in the model, a modification which significantly reduces the magnitude of the second LTD window (Shouval and Kalantzis 2005).

Spike-Timing Dependent Plasticity (STDP), Biophysical Models, Fig. 1 STDP according to Shouval et al. (2002). (a) $[\text{Ca}^{2+}]$ transients as described by Shouval et al. (2002) for four spike pairs. Presynaptic spike occurs at $t = 0$, and postsynaptic spike occurs at time interval as indicated in the legend. The only source of Ca^{2+} in the model is Ca^{2+} influx mediated by NMDARs. (b) Peak predicted $[\text{Ca}^{2+}]$ plotted against the spike-pair time interval. LTP and LTD peak $[\text{Ca}^{2+}]$ -signal threshold values, C_p and C_d , are illustrated showing plasticity outcomes for spike-pair

intervals from -100 ms to 200 ms. (c) The calcium-control hypothesis. Plot shows direction and magnitude of synaptic strength modification with $[\text{Ca}^{2+}]$ signal according to the calcium-control hypothesis (Shouval et al. 2002). LTD is predicted at moderate Ca^{2+} levels, and for large $[\text{Ca}^{2+}]$, LTP is the outcome. (d) STDP curve for spike pairs within range -100 ms to 200 ms as predicted by Shouval et al. (2002). Note the second LTD window at larger positive time intervals, an effect that is not observed in the majority of experimental STDP studies

Modelling Signalling Pathways

A key signalling pathway that has been identified in the mediation of NMDAR-dependent synaptic plasticity is the Ca^{2+} /calmodulin-dependent protein kinase II (CaMKII) signalling cascade (Lisman et al. 2002). Phosphorylation of CaMKII is linked with increased synaptic AMPAR number and conductance. Models of the complex CaMKII signalling pathway use Ca^{2+} signals to regulate the phosphorylation state of CaMKII. These models can exhibit a bistable switch-like behavior in the phosphorylation state of CaMKII (Fig. 2). This is due to the combination of a CaMKII autophosphorylation-generated positive-feedback loop in the signalling network and CaMKII activity inhibition by Ca^{2+} /calmodulin-dependent protein phosphatase 1 (PP1). Bistable models result in a synapse that exists in one of two states: a baseline state with synaptic AMPAR conductance magnitude corresponding to low levels of post-synaptic CaMKII phosphorylation and a

Spike-Timing Dependent Plasticity (STDP), Biophysical Models, Fig. 2 Bistable CaMKII switch. Concentration of phosphorylated CaMKII subunits as a function of the intracellular Ca^{2+} level. Stable states are indicated by solid red line, and unstable stationary states are indicated by dashed red line. Shaded region represents the $[\text{Ca}^{2+}]$ window within which both low and high CaMKII phosphorylation states are stable. Baseline $[\text{Ca}^{2+}]$ is indicated with vertical dashed black line showing stability of both high and low CaMKII phosphorylation states allowing maintenance of plasticity at normal intracellular levels of Ca^{2+} . LTP and LTD $[\text{Ca}^{2+}]$ signal windows are shown either side of the bistable region (Figure reproduced from Zhabotinsky (2000))

potentiated state corresponding to the second stable (high) phosphorylation level of CaMKII. The transition between the two states is triggered by intracellular $[\text{Ca}^{2+}]$, with moderate concentrations leading to low CaMKII phosphorylation states and high concentrations causing a transition to the highly phosphorylated state. This behavior corresponds with the Ca^{2+} -control hypothesis. A requirement for the maintenance of plasticity in CaMKII models is that the two CaMKII phosphorylation states must also be stable at baseline intracellular Ca^{2+} levels.

Castellani et al. (2005) is an example of a CaMKII-class, biophysical STDP model, describing induction of plasticity only since bistability is absent from the model. An early mathematical model of the CaMKII system that exhibits bistability in the phosphorylation states of CaMKII is detailed by Lisman and Zhabotinsky (2001). Studies that have used similar CaMKII bistable switching models, with particular application to STDP, include Graupner and Brunel (2007) and Urakubo et al. (2008). A more complicated signalling network is described by Jain and Bhalla (2009), whose model incorporates transcription and protein synthesis for the maintenance of LTP/LTD.

There is still some uncertainty as to whether NMDAR-dependent LTD/LTP is the same process acting in opposing directions or whether NMDAR-dependent LTD induction proceeds via a separate molecular signalling pathway to LTP induction. Models of cerebellar, non-NMDAR-dependent LTD do use a separate signalling pathway, which proceeds in a metabotropic glutamate receptor (mGluR)-dependent manner, ultimately leading to removal of AMPARs from the postsynaptic membrane and, hence, a reduction in synaptic transmission efficiency (Ito 2001).

Modelling Approaches

Over 100 biophysical models for synaptic plasticity exist in publication, most of which bear a resemblance to the models described in the above sections (Manninen et al. 2010). These models can be classified according to the various

methods used to create the model. For instance, many models have deterministic outcomes, while others include the stochasticity inherent in biochemical processes and have variable output. It is also possible to utilize a hybrid approach, incorporating stochastic and deterministic methods within the same model. Furthermore, some models take into account the spatial dependence of plasticity mechanisms since $[Ca^{2+}]$ signalling may be variable over the intracellular region to be modelled, whereas other models compress $[Ca^{2+}]$ signals to their time-dependent component only. Some biophysical STDP models include increased complexity, such that the outputs include spatial resolution of biological signals, and also variability across synapse populations (Manninen et al. 2010).

Synonyms

Spike-dependent synaptic learning rules; Spike-timing dependent synaptic plasticity; STDP

Definition

Biological phenomenon. Spike-timing-dependent plasticity (STDP) in its narrow sense refers to the

change in the synaptic strength as a result of repeatedly triggering pairs of action potentials (“spikes”) with a fixed time difference between the pre- and postsynaptic action potentials (Markram et al. 1997; Bi and Poo 1998; Sjostrom et al. 2001). STDP is typically observed for synapses between hippocampal or cortical pyramidal neurons in slices of juvenile rodents, and the spike pairings are repeated 50–100 times with various frequencies, e.g. 1 or 10 Hz. This protocol induces a change in the amplitude of a single excitatory postsynaptic potential (EPSP) which is plotted against the spike time difference $\Delta t = t_{\text{post}} - t_{\text{pre}}$ between the postsynaptic spike and the presynaptic spike (Fig. 1). The change takes in many cases a few minutes to be expressed and lasts at least for the duration of the experiment. Typically, when the presynaptic spike precedes the postsynaptic spike by roughly 10 ms, the synapse is potentiated; if the presynaptic spike follows the postsynaptic spike, the synapse is depressed (for reviews, see Bi and Poo (2001); Senn (2002); Sjostrom et al. (2008); Sjöström and Gerstner (2010)).

Spike-Timing Dependent Plasticity, Learning Rules, Fig. 1 Change of the EPSP amplitudes as a function of the time difference $\Delta t = t_{\text{post}} - t_{\text{pre}}$ between the post- and presynaptic spike. Time constants for LTP and LTD fits are $\tau_{\text{pre}} \approx 17$ ms and $\tau_{\text{post}} \approx 34$ ms, respectively (for an interpretation, see Fig. 2). Pairing protocol: 60 spike pairs at 1 Hz. Inset: postsynaptic action potential, relative to the time of the presynaptic spike (vertical line). Scale bars: 10 ms, 50 mV (Figure from Bi and Poo (2001))

Learning rules. In a computational context, STDP refers to plasticity rules that depend on the timing of pre- and postsynaptic spikes and that are involved in various learning scenarios for neuronal networks. These learning rules either emphasize the link to the biophysics underlying the synaptic modification (Senn et al. 2001; Shouval et al. 2002; Karmarkar and Buonomano 2002; Rubin et al. 2005; Graupner and Brunel 2012), or are minimalistic with respect to a biological implementation (Kempster et al. 2001; Song and Abbott 2001), or are derived from the maximization of a utility function (Pfister et al. 2006; Toyozumi et al. 2007; Florian 2007; Urbanczik and Senn 2009; Friedrich et al. 2011). The learning rules are studied in the context of supervised, unsupervised, or reinforcement learning. When evaluated from the performance point of view, learning rules that are mathematically derived from an optimization principle are superior over STDP rules designed to fit a given set of experimental data (Frémaux et al. 2010). Interestingly, biological plausibility and computational relevance may go together when considering 2-compartment neurons with synapses on a dendritic tree (Urbanczik and Senn 2014).

Detailed Description

STDP models come in different flavors, emphasizing more the phenomenology, the biophysics, or the computational aspects. As learning rules, their primary focus is on doing computations rather than on reproducing synaptic plasticity data. An excellent and comprehensive review to STDP models, starting with the basic pair-based STDP models (Fig. 2a) and including also functional consequences, is found in the Scholarpedia article by Sjöström and Gerstner (2010). Here we highlight the properties of third-order STDP models and focus on gradient rules.

Phenomenological STDP Models

The simplest online model that phenomenologically reproduces the basic STDP curve (Fig. 1)

Spike-Timing Dependent Plasticity, Learning Rules,

Fig. 2 Phenomenological STDP models. (a) Simplest model reproducing Fig. 1. (A1) Each presynaptic spike stepwise increases a presynaptic eligibility trace E_{pre} that otherwise exponentially decays to 0 with time constant τ_{pre} (Eq. 1). LTP is induced by each postsynaptic spike proportionally to the amount of E_{pre} available at that time. (A2) LTD is induced by each presynaptic spike proportionally to E_{post} that low-pass filters the postsynaptic spiking. Note that the post-pre-chain is itself acausal and does not appear in the gradient-based learning schemes represented in the subsequent figures. (b) Triplet rule. (B1) In the triplet model, LTP is induced at the time of the postsynaptic spike and is proportional to the product $E_{pre}E'_{post}$. (B2) In the triplet model, LTD is induced by pairs of spikes as in B1. (c) Weight change as a function of the repetition frequency of the pre-post pairs (solid lines, $t_{post} - t_{pre} = 10$ ms) and the post-pre pairs (dashed lines, $t_{post} - t_{pre} = -10$ ms). The triplet model (brown) fits well the data from (Sjostrom et al. 2001) (black) while the pair-based model (green) cannot

separately induces long-term potentiation (LTP) or long-term depression (LTD), by either a pre-post or post-pre-coincidence detector, respectively. The key feature is that pre- and postsynaptic spikings are each tracked by leaky integrators, the so-called synaptic eligibility traces, while LTP

and LTD are triggered proportionally to these traces at the times of the post- and presynaptic spikes, respectively (Fig. 2a, see also Sjöstrom and Gerstner (2010)).

The triplet model The simple STDP model which depends on pairs of spikes (pre-post and post-pre) correctly predicts the weight change only for a restricted number of protocols. If potentiation is assumed to be governed by triplets of spikes (pre-post-post) instead of pairs of spikes, a much broader class of experimental data can be captured (Pfister and Gerstner 2006). This so-called triplet model can be expressed as a sum of a depression term (Fig. 2B2) and a triplet term where at the time of the postsynaptic spike the weight change is proportional to the product of a postsynaptic and a presynaptic eligibility trace (Fig. 2B1).

The triplet model becomes especially relevant when the repetition frequency of the pre-post pairs increases. The pair-based model predicts a decrease of potentiation as a function of the pairing frequency. But in the visual cortex ($L5 \rightarrow L5$ pyramidal neurons, Sjostrom et al. (2001)), potentiation increases with increasing repetition frequency, and this is well reproduced by the triplet model (Fig. 2c; it is also qualitatively captured by the Senn-Markram-Tsodyks model; see Senn (2002)).

This triplet model has also interesting computational properties. Under the assumption of independent pre- and postsynaptic Poisson firing rate (Pfister and Gerstner 2006), the expected weight change predicted by the triplet model is consistent with the Bienenstock-Cooper-Munro (BCM) learning rule (Bienenstock et al. 1982) which elicits input selectivity, i.e., the output neuron becomes strongly responsive to one given (rate-based) input pattern and much less to all the other ones. Furthermore, if the independent Poisson assumption is relaxed such that output firing rate depends on the presynaptic spike timings, the triplet rule becomes sensitive to third-order spiking correlations in the input, thereby generalizing the BCM learning rule to spiking-correlated patterns (Gjorgjieva et al. 2011).

Extended models A next important extension of STDP models takes account of the modulation

of plasticity by the postsynaptic voltage (Clopath et al. 2010; Clopath and Gerstner 2010). This unifying model is formulated in terms of the postsynaptic voltage time course and presynaptic spikes. It can explain the widest set of STDP experiments, including burst-induced synaptic plasticity and those experiments that reveal the dependence on the postsynaptic voltage, as e.g. in Artola et al. (1990) and Sjostrom et al. (2001). This voltage-dependent model can also be seen as an extension of the triplet model where the postsynaptic eligibility trace in the potentiation term is replaced by a low-pass filter of the postsynaptic voltage. The triplet model, in turn, can be seen as a simplified version of the model by Senn et al. (2001). This latter model also depends on triple events (pre-post-post) for the induction of long-term potentiation, but the pre-post-post ordering is important while in the triplet model both pre-post-post as well as post-pre-post events lead to potentiation.

Biophysical STDP models Another class of STDP models explains the synaptic modifications as a nonlinear function of the postsynaptic calcium concentration. The question whether the postsynaptic calcium alone can capture the characteristic STDP curve of Fig. 1 (see Shouval et al. (2002) versus Karmarkar and Buonomano (2002)) has been affirmed by taking into account the calcium dynamics (Rubin et al. 2005) or additional nonlinearities (Graupner and Brunel 2012). Functionally, these threshold nonlinearities are very similar to the ones imposed on the pre- and postsynaptic eligibility traces introduced in the phenomenological models (Senn et al. 2001; Clopath et al. 2010). Yet, by starting with individual protein kinetics, a biophysical model may explain how these nonlinearities arise (Rubin et al. 2005), see also ► “Spike-Timing Dependent Plasticity (STDP), Biophysical Models.”

Gradient-Based STDP Learning Rules

By their nature, the phenomenological and biophysical STDP models are not directly designed as synaptic learning rules that solve an explicit learning task. When canonical target functions for

the learning can be defined, such as in the supervised and reinforcement learning scenario, spike-timing-dependent learning rules can be derived from gradient procedures that maximize/minimize these functions. A very convenient neuron model suited for a theory of learning is the escape rate neuron. Indeed since it allows to explicitly quantify the probability for a given postsynaptic spike train as a function of the afferent synaptic strengths w_j , the likelihood of a given spike train is differentiable (w.r.t to w_j) (Pfister et al. 2006). This neuron stochastically emits spikes with instantaneous firing rate $\rho(u)$ that is an increasing function of the instantaneous membrane potential $u(t)$. The latter is itself a sum of the postsynaptic potentials (PSPs) weighted by the synaptic strengths, $u(t) = \sum_j w_j \text{PSP}_j(t)$, optionally subtracted with a reset kernel after a postsynaptic spike.

Supervised learning In the supervised learning scenario, the target function can be defined as a distance between the desired postsynaptic spike train, $S_{\text{post}}^{\text{cl}}(t) = \sum_i \delta(t - t_i^{\text{post}})$, that is clamped as an output to the neuron and the spike trains that would be generated by the neuron itself. If we pick out a specific synapse, the presynaptic eligibility trace $E_{\text{pre}}(t)$ is again obtained by the leaky integration of the presynaptic spike train $S_{\text{pre}}(t) = \sum_i \delta(t - t_i^{\text{pre}})$. Typically, the integration time constant τ_{pre} is equal to the membrane time constant, and hence this trace can also be identified with the postsynaptic potential induced by that synapse, $E_{\text{pre}}(t) = \text{PSP}(t)$. The gradient rule that maximizes the log-likelihood of reproducing the clamped target spike trains is then obtained as (Pfister et al. (2006); see Fig. 3a).

$$E_{\text{pre}}(t) = \int_{-\infty}^t S_{\text{pre}}(\tilde{t}) e^{-\frac{t-\tilde{t}}{\tau_{\text{pre}}}} d\tilde{t} \quad (1)$$

$$\dot{w}(t) = \eta \frac{\rho'}{\rho} \left(S_{\text{post}}^{\text{cl}}(t) - \rho(u(t)) \right) E_{\text{pre}}(t), \quad (2)$$

where η is some small learning rate. Here, $\rho' = \rho'(u(t))$ is the derivative of the escape rate ρ with respect to u , evaluated at t . Interestingly, by expressing Eq. 2 as a sum of a potentiation and a

Spike-Timing Dependent Plasticity, Learning Rules, Fig. 3 Gradient-based SDTP for supervised learning (a, b) and unsupervised learning (b). (a) An optimal learning rule that reproduces the timing of a given (“clamped”) output spike needs to take account of the postsynaptic membrane potential u beside the pre- and postsynaptic spikes (Eqs. 1 and 2). (B1) In a biological version, u is only slightly “nudged” by excitatory and inhibitory conductances g_E and g_I . The strength of synapses on the dendrites is adapted such that the dendritic potential V converges to the nudged somatic potential u . (B2) The corresponding gradient rule yields LTP that does only depend on the pre-post spike timings and LTD that depends only on the presynaptic spike time (captured by E_{pre}) and the local dendritic voltage (V ; see Eqs. 1 and 3)

depression term, we note that potentiation depends on three factors (the postsynaptic spike, the presynaptic eligibility trace, and a nonlinear function of the postsynaptic membrane potential $\rho'(u)/\rho(u)$) and depression on two factors (the presynaptic eligibility trace and $\rho'(u)$). This learning rule is reminiscent of the voltage-triplet rule discussed above (Clopath and Gerstner (2010); see also Brea et al. (2013) for a detailed discussion of the mapping between those two learning rules).

Arguably, clamping the postsynaptic spike train S_{post}^{cl} is biologically unfeasible as it would require that the membrane potential u is ∞ at the time of a target spike and $-\infty$ else, conflicting with the evaluation of ρ and ρ' at the synaptically generated value of u . An alternative is to separate the spike-generating voltage from the synaptically

induced voltage and consider a somatic and dendritic membrane potential, u and V , that are interpreted as a “teacher” (u) and “student” (V) potential, respectively (Fig. 2B1; Urbanczik and Senn (2014)). The soma receives conductance-based synaptic input that represents a teaching signal, and the postsynaptic spike train S_{post} is stochastically generated in the “free” run, i.e., according to a firing intensity $\rho(u)$ that is affected by this teaching input. Without teaching input, the somatic membrane potential is just the attenuated dendritic voltage, $u = \alpha V$, where α represents some dendritic attenuation factor and the instantaneous somatic firing is therefore $\rho(\alpha V)$. But if the somatic teaching input is turned on, the somatic voltage typically differs from the “dendritic prediction,” $u \neq \alpha V$. Learning is driven by the “prediction error” measured in terms of the firing rates, $\rho(u) - \rho(\alpha V)$. It reduces this error by adapting the synaptic strengths of the dendritic “student inputs.” At the synaptic location on the dendrite, the somatic rate $\rho(u)$ can be sampled by the backpropagating spikes S_{post} . The learning rule (Eq. 2) now translates to the biological version

$$\dot{w}(t) = \eta \frac{\rho'}{\rho} (S_{post}(t) - \rho(\alpha V(t))) E_{pre}(t). \quad (3)$$

that can operate all the time, without need for clamping (Fig. 2B2).

Crucially, after learning the teaching input driving, the synaptic plasticity (Eq. 3) can be turned off or on, without affecting the somatic voltage and hence without inducing additional weight changes. This is a consequence of the conductance-based teacher input that itself only changes the membrane potential if it deviates from the reversal potential defined that teaching input (Urbanczik and Senn 2014). The rule shares other interesting biological features. When the backpropagation is hampered, say due to insufficient dendritic depolarization, S_{post} is thinned out at the synaptic site and a putative LTP turns into LTD, as observed for synapses on the distal apical tree of cortical pyramidal neurons (Sjostrom and Häusser 2006). Similarly, when the dendritic depolarization V is enhanced without additional postsynaptic

spikes, LTD dominates as observed for these same cells (Sjostrom et al. 2004).

Unsupervised learning The learning rule (Eq. 2) in the free run is itself not suited for unsupervised learning since averaging $\dot{w}$ across trials cancels out to 0 at each point in time. However, if we consider a 2-dimensional sheet of 2-compartmental neurons as described in Fig. 2b, with Mexican-hat shaped somato-somatic connections, the somatic potential u is nudged away from V^* and the somatic firing in average does not anymore reflect the dendritic drive, $\langle S_{\text{post}} \rangle \neq \rho(V^*)$. In this case, the lateral connectivity induces a soft winner-take-all dynamics in the network that becomes a spike-based self-organizing feature map (Urbanczik and Senn 2014). When the dendrites of these neurons are supplied by spatiotemporal spike patterns via plastic synapses governed by the rule (Eq. 3), the feature map learns to cluster the spike patterns according to their similarity.

Another form of a gradient-based unsupervised learning that maximizes the mutual information between the pre- and postsynaptic spike trains was also shown to share classical STDP features while being able to develop receptive field properties (Toyoizumi et al. 2007). In the unsupervised setting, functional properties have also been shown for phenomenological STDP models in forming auditory maps (Gerstner et al. 1996), cortical columns (Song and Abbott 2001), direction-selective neurons in the visual cortex (Buchs and Senn 2002), or receptive fields similarly as described in the BCM theory (Gjorgjieva et al. 2011).

Reinforcement learning In reinforcement learning (RL), the putative synaptic weight changes induced by the pre- and postsynaptic activities are first low-pass filtered, and when a binary reward signal $R = \pm 1$ is applied, the changes accumulated until this time are multiplicatively modulated by R and turned into a real synaptic weight change. The phenomenological STDP model shown in Fig. 2 has also been adapted to this reinforcement learning scenario where it is referred to as R-STDP (Izhikevich 2007; Legenstein et al. 2008). However, R-STDP is shown to be problematic since for each stimulus class the expected reward must be

0 (Frémaux et al. 2010). This is because the integral over the STDP curve (Fig. 1) in general deviates from 0, and hence learning with $\langle R \rangle \neq 0$ would cause a weight drift. This is not the case for Eq. 2 in the free run, nor for Eq. 3 without somatic teaching conductances. These latter rules translate to the RL rule schematized in Fig. 4b:

$$E_{\text{post}}(t) = \int_{-\infty}^t \frac{\rho'}{\rho} (S_{\text{post}}(\tilde{t}) - \rho(u(\tilde{t}))) E_{\text{pre}}(\tilde{t}) e^{-\frac{t-\tilde{t}}{\tau_R}} d\tilde{t} \quad (4)$$

$$\Delta w(T) = \eta R E_{\text{post}}(T), \quad (5)$$

Gradient rules for RL

Spike-Timing Dependent Plasticity, Learning Rules, Fig. 4 Gradient-based SDTP for reinforcement learning (RL). With incorporating downstream quantities into the synaptic plasticity, learning becomes faster. (a) The simplest spike-based RL rule changes the presynaptic release probability p (a proxy for the synaptic strength w) as a function of the presynaptic spike and the release, low-pass filtered with a time constant τ_R corresponding to the typical reward delay (Seung 2003). (b) The same synaptic modifications for supervised learning (Fig. 3) yields RL when low-pass filtered with τ_R and modulated with the delayed reward R (Eqs. 1, 4, and 5). (c) As a decision is made by a population of neurons, synaptic updates should take account of the population decision signal D_{pop} , compare it with the single neuron decision D_{post} , low-pass filter the correlation between the two decision signals with τ_R , and only then implement the resulting weight change modulated by R (Eqs. 1, 6, 7, and 8)

where E_{pre} is given in (Eq. 1) and for the 2-compartmental model, the argument u of ρ and ρ' is replaced by V^* . The rule is shown to perform stochastic gradient ascent on the expected reward and has been studied in different applications (Xie and Seung 2004; Pfister et al. 2006; Florian 2007; Frémaux et al. 2010).

Stochastic gradient rules are not unique since the same gradient can be obtained from different estimators. The rule in Eq. 5, for instance, represents an estimator of the gradient of the expected reward, $\frac{\partial}{\partial w} \langle R \rangle = \langle R \frac{\partial}{\partial} \log P_w(y|x) \rangle$, averaged across stimuli x , network activity y , time and reward. The reward R may depend on quantities downstream of x and y like the decision (or action) D that itself may stochastically depend on y . The reward $R(x, y)$ therefore is a stochastic function of (x, y) with conditional expectation $\langle R|x, y \rangle = \sum_D R(x, D)P(D|x, y)$. For a synapse that has only access to the pre- and postsynaptic activities (components of x and y), the samples $R(x, y)$ have a large variance and so will the samples $R(x, y) \times \frac{\partial}{\partial w} \log P_w(y|x)$ of the gradient estimate have. In contrast, $R(x, D)$ may be a deterministic function (or again a stochastic function with smaller variance) and the samples $R(x, D) \frac{\partial}{\partial w} \log P_w(D|x)$ of the same reward gradient $\frac{\partial}{\partial w} \langle R \rangle$ show a smaller variance. To calculate $\frac{\partial}{\partial w} \log P_w(D|w)$, however, a synapse needs to have access to D (beside the pre- and postsynaptic activities).

Instead of considering $R(x, y)$, the reward can even be seen as a stochastic function of only the presynaptic spikes and the synaptic releases, $R(x, \text{rel})$. This leads to a learning rule where synaptic releases that are correlated with subsequent rewards are made more likely by enhancing the corresponding release probability (Seung 2003). But the variance of this reward gradient estimator can be reduced by taking account of the postsynaptic activity. In this way, more and more downstream information can be taken into account in the synaptic update, leading to learning rules that consider (A) only presynaptic spikes/releases and reward, (B) presynaptic spikes/releases, postsynaptic activity and reward, and (C) presynaptic spikes/releases, postsynaptic activities, single neuron and network decisions, and reward

(Fig. 4). In these gradient estimators, the correlation between the synaptic parameter change and reward is progressively increased the more reward-relevant information the synapse exploits. In the case of only evaluating presynaptic spikes and releases, learning was claimed to mimic song acquisition in the zebra finch (Seung 2003). When additionally evaluating the postsynaptic spikes and the membrane potential, the rule was shown to learn motor trajectories (Frémaux et al. 2010). When further evaluating the population decision the rule was shown to be successful in a complex sequential association task with delayed and scrambled rewards that is even hard to be learned by humans (Friedrich et al. 2011).

In population RL, the synaptic plasticity is modulated by the population decision that ultimately leads to the reward signal (Urbanczik and Senn 2009). The sign of the weight change should depend on whether the decision of the individual postsynaptic neuron D_{post} coincides with population decision D_{pop} formed by the majority of population neurons. These signals intrinsically depend on the neuronal code with which neurons and populations represent the possibly multi-valued decisions and actions (Friedrich et al. 2014). In the simplest case of binary decisions, these signals may be set to 1 or -1 , depending on whether the neuronal or population activity, low-pass filtered by τ_{Dec} , is above or below the corresponding decision threshold (Friedrich et al. 2011). The gradient rule emerging from this reasoning reads as (cf. Fig. 4c)

$$E_{\text{post}}(t) = \int_{-\infty}^t \frac{\rho'}{\rho} (S_{\text{post}}(\tilde{t}) - \rho(u(\tilde{t}))) E_{\text{pre}}(\tilde{t}) e^{-\frac{t-\tilde{t}}{\tau_{\text{Dec}}}} d\tilde{t} \quad (6)$$

$$E_{\text{Dec}}(t) = \int_{-\infty}^t D_{\text{post}}(\tilde{t}) D_{\text{pop}}(\tilde{t}) E_{\text{post}}(\tilde{t}) e^{-\frac{t-\tilde{t}}{\tau_{\text{R}}}} d\tilde{t} \quad (7)$$

$$\Delta w(T) = \eta R E_{\Delta \varepsilon_X}(T). \quad (8)$$

Intracellular recordings from dendrites during plasticity induction protocols have shown that SDTP also depends on dendritic NMDA spikes

(Gordon et al. 2006). This raises the question whether there are spike-timing-dependent plasticity rules that take account of such dendritic spikes as well. There is in fact a class of gradient-based RL rules that incorporate the “triple-spike timing” among the presynaptic, dendritic, and postsynaptic spike sequence, including the dendritic and somatic voltage and the reward modulation, analogously to the four-step cascade schematized in Fig. 4c (Schiess et al. 2012).

Definition

Spinal cord refers to the central nervous system (CNS) in vertebrates below the foramen magnum,

between the brainstem and the peripheral nervous system, not including the autonomic ganglia.

Learned sensorimotor behavior refers to all types of voluntary musculoskeletal activation that accomplish a behavioral goal and that utilize sensory feedback during execution, but here excluding cyclical locomotor behaviors known to be generated and controlled autonomously by central pattern generators residing within the spinal cord itself (see “Cross-References”).

Detailed Description

The spinal cord is not part of the brain; together they constitute the central nervous system of vertebrates. The spinal cord alone is capable of controlling complete motor behaviors such as locomotion. It can generate complex sequences of muscle activation and alter them to ambient conditions detected by somatosensory afferents. The well-studied role of the spinal cord in locomotion is covered in other entries (► [“Vertebrate Pattern Generation: Overview”](#)); this article considers whether and how the same spinal circuits contribute to voluntary motor behavior that is ultimately controlled by the brain.

Historical and Methodological Perspective

Several anatomical features of the spinal cord made it an attractive target for the earliest neurophysiological investigations. Its connections to and from the peripheral nervous system of the body are arranged in four laterally and dorsoventrally segregated and highly elongated rows of roots. These are divided and gathered into spinal nerves based on the openings between adjacent vertebrae. These roots and their associated peripheral nerves are readily traced by gross anatomical dissection to various target structures (individual muscles and regions of skin) whose function can be easily observed and manipulated. About 200 years ago, the anatomist Charles Bell and, separately, the physiologist Francois Magendie discovered that the ventral roots conveyed the motor commands to the

muscles (Bell 1811) while the dorsal roots conveyed only sensory information (Magendie 1822), respectively. This laid a foundation for the interpretation of clinical phenomena such as the knee-jerk reflex, well known to nineteenth-century neurology. At the turn of the twentieth century, Sir Charles Sherrington systematically extended the set of spinal reflexes to include both excitatory and inhibitory responses as well as interlimb effects and suggested that such reflexes constituted the building blocks of spinally mediated behaviors such as locomotion (Sherrington 1910).

As electrophysiological methodology developed during the middle of the twentieth century, it became possible to identify the individual neurons and circuits responsible for behavioral phenomena. The spinal interneurons came to be divided and identified by the nature of the input and output connections by which they were first identified. The newly discovered proprioceptors and spinal interneurons appeared to correspond to the feedback circuits utilized by the emerging field of servo control engineering to stabilize electrical and mechanical systems (including the instrumentation that those electrophysiologists generally had to build for themselves). This suggested that the reflexes might be just the most visible manifestations of continuous servo control, in which the spinal circuitry could simplify the problem of motor control by linearizing the complex mechanical properties of the musculoskeletal system (Houk 1979). It gradually became clear, however, that the actual input and output connections to spinal interneurons and motoneurons were far broader than predicted by servo control. The most local circuits were the easiest to find but the cumulative effects of the more widespread circuits are probably much larger. Furthermore, the strength and even the sign of many spinal reflexes were found to be modulated during both locomotor and voluntary motor behaviors (Burke 1999).

Neurophysiological studies of voluntary behaviors have focused mostly on the cerebral cortex of the brain, correlating neural activity recorded by chronically implanted

microelectrodes with observable kinematics and/or muscle activity in the limb. However, the vast majority of corticospinal projections end on spinal interneurons rather than the motoneurons that activate muscles directly (Rathelot and Strick 2009). These interneurons are vigorously active during learned, voluntary limb movements (see Fig. 1 below from Perlmuter et al. 1998). The threshold nonlinearity of spiking neurons implies that the cortical commands can be seen as enabling reflexive adjustments or, equally, that the ongoing somatosensory feedback enables the commanded behavior. Early attempts to tease this apart relied on the latencies of various responses to strong electrical stimuli, which depend on the physical lengths of the circuits and the conduction velocities of the axons. This can be used to compute the minimal latency of the fastest possible responses such as the monosynaptic stretch reflex, but it does not help with mechanical stimuli whose asynchronous afferent signals may undergo substantial temporospatial integration in the interneurons at every level before any response is seen.

This entry summarizes what is now known about the connectivity of the spinal circuits (for a detailed review, see Pierrot-Deseilligny and Burke 2005). Much of that information comes from histological tracing and electrophysiological studies of the spinal cord of the cat, supplemented by clinical studies of human limb reflexes. There are substantial specializations in other species and other parts of the body such as the axial muscles of the neck and trunk (Richmond and Loeb 1992). This review also considers theories and models regarding how these spinal circuits could contribute to control of learned, voluntary limb movements. Other parts of the brain such as the cerebellum have equally well-developed connections to and from spinal cord (Spanne and Jörntell 2013) compared to the cerebral cortex. Damage to the cerebellum produces different but equally profound sensorimotor disorders, but its role in voluntary behavior is even less well understood. The actual functional relationships between the brain and the spinal cord remain contentious.

Spinal Cord, Integrated (Non CPG) Models of, Fig. 1 Extracellularly recorded spikes from a spinal premotor interneuron recorded as monkey-generated isometric ramp-and-hold torques in flexion and extension at the wrist in order to match a visual cue; *FDS* = EMG from

flexor digitorum superficialis, *ECU* = EMG from extensor carpi ulnaris. Note strong correlation with ECU during extension torques but substantial activity during flexion torques that was not correlated with *FDS* modulation (From Perlmuter et al. 1998)

Basic Components

Somatosensory Afferents

A general review of somatosensation can be found elsewhere; this is a brief summary of the afferents whose modalities and conduction velocities resulted in the naming conventions for the interneurons described below.

- **Spindle Primary Afferents (Ia):** Most muscles contain 20–500 elaborate sense organs attached in parallel with their muscle fibers. These muscle spindles each contain several specialized and separately innervated intrafusal muscle fibers. Each spindle is innervated by one rapidly conducting, primary afferent axon ($A\alpha$) whose local sensory endings consist of spirals wrapped around the middle of each of the intrafusal muscle fibers. These Ia afferents are exquisitely sensitive to stretch of the muscle (and hence of the spindle and its intrafusal muscle fibers). The absolute and relative sensitivities of the Ia afferents to length versus velocity are modulated over a wide dynamic range by centrally controlled activation of their various types of intrafusal muscle fibers (Loeb 1984).
- **Golgi Tendon Organ (GTO) Afferents (Ib):** Most muscles contain 20–200 simple sense organs attached in series with various subsets of their muscle fibers, making them sensitive to active muscle force. Each GTO is innervated by one rapidly conducting primary afferent axon ($A\alpha$). The random sampling of muscle fibers makes the response of a given GTO somewhat idiosyncratic, but the generally orderly recruitment of motor units results in ensemble activity of the Ib afferents that accurately reflects total muscle force (Mileusnic and Loeb 2009).
- **Group II Afferents:** The smaller and slower conducting myelinated axons ($A\beta$) in peripheral nerves are designated as Group II. They include both cutaneous mechanoreceptors with a wide range of sensitivities in both glabrous and hairy skin plus secondary spindle afferents attached to a subset of the intrafusal muscle fibers and sensitive mostly to absolute length.

Some cutaneous stretch sensors contribute to the sense of body posture and motion in combination with the spindle afferents (Gandevia 1996); others are better suited to detecting intermittent contact with external objects.

- **Group III and IV Afferents:** The smallest myelinated ($A\delta$) and unmyelinated (C) sensory nerve fibers innervate a wide range of specialized receptors for strain, temperature, pain, and metabolic products. Their signals are processed locally by dorsal horn interneurons, many of which project to some of the spinal interneurons or their presynaptic inputs. Their slow conduction velocities lead to the presumption that they do not contribute importantly to moment-to-moment coordination but they probably modulate the state of the system in response to fatigue and injury (Martin et al. 2006).
- **Recurrent Motoneuron Collaterals:** Most alpha motoneurons give off collateral branches before leaving the spinal cord en route to the muscles. While not truly sensory, these efference copy signals provide feedback regarding important state variables of the system, contributing to both the reflexive behavior of the spinal cord itself and the ascending information that is conveyed to the brain (Windhorst 1990).

Presynaptic Modulation

An important feature of many spinal circuits is the presence of synaptic triads, in which the synaptic boutons of one neuron (modulator) end on the boutons of another neuron (transmitter) rather than on the cell body or dendrites of the receiver neuron. These presynaptic pathways may exert either depolarizing or hyperpolarizing effects on the resting membrane potential of the transmitter boutons. When a spike arrives at the transmitter bouton, the amplitude of the voltage excursion depends on this resting potential; the amount of transmitter that is released depends strongly on the voltage excursion. A depolarizing presynaptic modulation thus has the effect of inhibiting the efficacy of the transmitter; a hyperpolarizing modulation facilitates the transmitter. The presynaptic inhibitory effects of many cutaneous afferents

have been particularly well described (Rudomin and Schmidt 1999). The monosynaptic stretch reflex is also presynaptically inhibited by descending cortical pathways (Meunier and Pierrot-Deseilligny 1998) and in fatigued muscles (Baudry et al. 2010). The full extent of sources and recipients of presynaptic inhibition and facilitation is not known.

Limb Dynamics

Physiologists look for ways to simplify complex musculoskeletal anatomy and mechanics in order to identify organizing principles of control. By focusing on one axis of motion of one joint (e.g., dorsiflexion/extension of the ankle joint), it is possible to describe all the muscles that create a positive moment as synergists and all that create a negative moment as antagonists. Activation of the muscles in each group will have opposite effects on the joint torque, and motion of the joint in this axis will have opposite effects on the stretch receptors in these two groups of muscles. Unsurprisingly, the reflexes elicited by afferents from synergistic muscles are substantially different and often opposite in sign from those elicited by the same types of afferents from the antagonist muscles (Sherrington 1908). Much of the terminology below reflects this natural reciprocity of function and connectivity.

Unfortunately, most musculoskeletal anatomy and dynamics are not well described by simple reciprocity. Most joints have more than one axis of motion and the majority of mammalian muscles cross more than one joint. The lengths of the muscles and their moment arms on each axis of motion depend on the posture and motion of all the axes of all the joints that they cross. Muscles that are synergists for the restricted motion described above may be undergoing length changes that are opposite in sign and generating torques in other axes that are opposite in sign. Furthermore, a skeleton consisting of a series of linked inertial masses is subject to intersegmental dynamics, sometimes summarized as Coriolis effects. Acceleration induced by a muscle crossing one joint results in angular accelerations at distant joints, similar to the complex sequence of motion

induced by cracking a whip from its proximal end (Zajac and Gordon 1989). The idealized classical circuits described below use the terminology of synergist and antagonist, but most muscles relate to most other muscles via combinations of both types of circuitry (designated as a “partial synergist” relationship). The net effects depend on the gains in the competing pathways, which are strongly modulated by both descending and local pathways, as discussed in Coordination and Regulation.

Spinal Circuits

Ia Monosynaptic Stretch Reflex

The tendon jerk reflexes (e.g., knee, ankle) are the fastest and most reliable responses because they involve only one synapse between a rapidly conducting Ia spindle afferent and an alpha motoneuron. The Ia afferents from a given muscle project to most or all of the motoneurons that control that muscle (homonymous projection; HOM in Fig. 2) and to many of the motoneurons of synergist (SYN) muscles (Eccles et al. 1957a). Nevertheless, the strength of the observable response can be substantially modulated by post-synaptic polarization of the receiving pool of motoneurons via other synaptic inputs and by presynaptic inhibition or facilitation of the Ia synapse itself. The brain can learn to change the gain of even this direct connection (Wolpaw 2010).

Ia Inhibitory Interneurons

Spindle Ia afferents excite a class of inhibitory interneurons that project to the motoneurons of antagonist muscles (Eccles and Lundberg 1958). Thus, stretching one muscle tends to inhibit activity that may be occurring in the antagonist muscles and that would otherwise oppose the excitatory stretch reflex described above. It is important to remember that the spindle receptors of both the synergist and antagonist muscles are generally biased by their respective fusimotor efferents so that they are generating continuous activity. Sudden perturbations that give rise to excitatory and inhibitory reflexes are just the

Spinal Cord, Integrated (Non CPG) Models of, Fig. 2 Five classical interneuronal pathways that comprise the model from the perspective of a single muscle. Projections from neural elements associated with self (*HOM*) as well as synergist (*SYN*) and antagonist (*ANT*)

muscles are shown with color codes: Ia inhibitory interneurons are *blue*, Ib inhibitory interneurons are *orange*, and Renshaw inhibitory interneurons are *black* (Illustration from Tsianos et al. 2011)

most obvious manifestation of a continuous push-pull servo control system. These reciprocal circuits work continuously to maintain stable body posture and minimize energetically wasteful cocontraction of mutually antagonistic muscles.

Ib Inhibitory Interneurons

The force-sensitive Golgi tendon organs excite a class of inhibitory interneurons that project to their own and synergist motoneurons (Eccles et al. 1957b). This results in a simple servo controller that tends to stabilize fluctuations in force. The story does not end there, however. The Ib inhibitory interneurons actually receive inputs from a wide range of cutaneous and proprioceptive afferents, and they project widely to both synergistic and antagonistic motoneurons. Furthermore, Ib inhibitory interneurons project to

each other, resulting in disinhibition whereby force feedback can actually result in positive, self-reinforcing feedback loops (McCrea 1986). This complexity is summarized in Fig. 2 (Ib, bottom right) and Fig. 3 with a symbol denoting the selectability of both excitatory and inhibitory effects between the Ib inhibitory interneuron and homonymous alpha motoneuron.

Renshaw Inhibitory Interneurons

The recurrent motoneuron collaterals excite an interneuron that inhibits the homonymous motoneurons and their synergists, in the manner of a servo control governor preventing runaway activation of the muscles. These Renshaw inhibitory interneurons also project to the Ia inhibitory neurons of the same muscle, resulting in a disinhibition of the antagonist motoneurons (Windhorst 1990).

Spinal Cord, Integrated (Non CPG) Models of, Fig. 3 The major proprioceptive feedback circuits between two wrist muscles that are synergists for some tasks (e.g., extension) and antagonists for others (e.g., radioulnar deviation); color code is the same as in Fig. 1.

Tasks were controlled by learning a background pattern of *SET* signals to designated spinal neurons and presynaptic gains (*S* in circles) and a *GO* pattern to initiate the task via only the spinal interneurons (Figure from Raphael et al. 2010)

Propriospinal Excitatory Interneurons

There are clusters of excitatory spinal interneurons located just rostral to both the cervical and lumbar enlargements wherein the limb motor nuclei are located. These interneurons receive direct excitatory projections from both Ia and Ib afferents as well as strong descending control from the brain (Jankowska et al. 1973). They have been implicated in the initiation of voluntary limb movements via their excitatory and inhibitory effects on synergist and antagonist motoneurons, respectively (Lundberg 1992).

Cutaneous Reflex Interneurons

Activity in cutaneous afferents can produce strong and widely distributed excitation and inhibition of motoneurons. The pathways all go through chains of at least two interneurons, however, each of which is subject to modulation by other afferents, other interneurons, and descending signals from the brain. The functional contribution of cutaneous feedback is obvious from studies of dexterous manipulation of objects (Johansson and Flanagan 2009), but specific circuit models are not available.

Spindle Secondary Interneurons (Group II)

The tonic stretch reflex and perhaps some of the knee-jerk reflex may be generated by disynaptic excitation arising from Group II muscle afferents. These same interneurons also receive input from Flexor Reflex Afferents (see below). It has been proposed that these Group II interneurons and others resulting in disynaptic inhibition contribute to voluntary behaviors (Lundberg et al. 1987), but there is little direct evidence as yet.

Flexor Reflex Afferents

Nociceptive cutaneous afferents (Group III = A δ fibers, Group IV = C fibers) give rise to the flexion reflex, consisting of coordinated activation of ipsilateral limb flexors and often accompanied by contralateral limb extension (Anden et al. 1964; Duysens et al. 2013). It is prominent during locomotion, enabling the limb to withdraw from an obstructive or aversive stimulus to get around an obstacle. Specific models of these oligosynaptic circuits are not available.

Commissural Interneurons

Interneurons that project across the midline appear to be useful for interlimb coordination during locomotion (Jankowska 2008). Specific circuit models are not available and their role in learned motor behaviors is unknown.

Central Pattern Generators (CPG)

As discussed elsewhere (McCrea and Rybak 2008), the spinal cord contains reciprocally inhibited groups of interneurons that function as self-sustaining oscillators for cyclical behaviors such as locomotion. Their relatively simple, alternating rhythms are converted into the more subtly phased activation of individual muscles by the interneuronal circuits listed above and perhaps unknown others. Their rhythms can be altered or even reset by somatosensory feedback and descending control. It is unknown whether these CPG circuits are utilized for learned motor behaviors that have similar oscillatory patterns.

Decision and Command Versus Coordination and Regulation

The general notion is that the brain is strategic, deciding what voluntary movement should be executed and when, while the spinal cord is tactical, dealing with the details of apportioning the physical work among various muscles and making reflexive adjustments to cope with local conditions. Most of the theories described below were motivated by the desire to simplify these problems, both so that the process could be understood by researchers and so that the brain could actually solve them. Nevertheless, from the relatively slow rate at which infants develop motor coordination, it is apparent that this is a very hard problem requiring a great deal of adaptive learning by the brain. Simple and intuitive theories may not be consistent with reality.

Fusimotor Servo Control

If the brain plans movements according to the desired trajectory of limb postures, then there has to be a computation to convert that plan into the net drive to each of the muscles required to stay on that trajectory. The complex mechanical dynamics of a multiarticular limb plus the highly nonlinear force-generating properties of muscle make such a calculation difficult, to say the least. Servo control offers a way out of this dilemma. Muscle activation could be commanded (or at least assisted) by first activating fusimotor neurons, thereby turning on muscle spindle afferents, and then allowing the excitatory reflexes from those afferents to turn on the motoneurons until the muscle shortened to the point where the fusimotor effects were negated (Merton 1953).

These ideas have fallen out of favor for two reasons. One is the lack of evidence for sufficiently high gains in these pathways or for fusimotor drive and spindle afferent activity that clearly leads the alpha motoneuron activity. The second is the recognition that the spindle afferents are responsible for much of the senses of posture and kinesthesia (Scott and Loeb 1994), which must be independent of muscle activation. It seems more likely that the fusimotor system is used to optimize the sensitivity of the spindle

afferents to the expected range of voluntary movements, thereby improving rather than degrading these critical senses (Loeb and Marks 1985).

Reciprocal and Equilibrium Control

Another way to solve the above-stated problem of getting a complex musculoskeletal system into the desired posture is to take advantage of the spring-like properties of mutually antagonistic sets of muscles at each joint. Active muscles themselves tend to behave like springs, increasing their force output when stretched and decreasing it when shortened. Simply coactivating mutually antagonistic muscles at different levels necessarily results in various postures (Bizzi et al. 1993); perturbations away from those postures are automatically resisted by the effective mechanical impedance of the system (which includes spring-like terms related to joint angle plus terms related to joint velocity and acceleration (Hogan 1984)). The ability of such a control system to follow dynamic trajectories can be greatly enhanced by including the reciprocal reflexes mediated by spindle afferents, and they can be more subtly modulated by further including fusimotor control. This is the so-called gamma equilibrium-point hypothesis (Feldman 1966; Feldman et al. 1998). A more general model of how the brain could utilize the reciprocally organized spindle feedback was presented by Maier et al. (2005).

While these muscle properties and reflexes certainly affect the properties of the system that the brain must control, they do not by themselves seem to account well for many observed behaviors (Kistemaker et al. 2007). Equilibrium control predicts more inefficient and undesirable cocontraction of muscles than is generally observed. It has difficulty with highly dynamic movements or when the goal is to control force on an object or surface rather than position. Finally, it is difficult to extend these schemes to account for the many multiarticular muscles and for the intersegmental dynamics of limbs.

Inverse Dynamics Models

Presumably the brain generates the command signals to the spinal cord that will result in the desired limb trajectory. If the brain were sending signals

directly to the motoneurons, it could learn an inverse model of the musculoskeletal mechanics and then employ an optimization scheme to compute an effective and efficient pattern of commands (Kawato 1999; Scott and Norman 2003). It would also have to monitor the sensory feedback and compute the necessary adjustments (Scott 2004), suppressing or taking into account any reflexes that would be occurring simultaneously in the autonomous circuits of the spinal cord (and probably other lower centers). But the brain is largely sending signals to the spinal interneurons themselves. In order to compute those commands, the brain would require an inverse model that included also the connectivity of the interneurons plus a forward model of the sensory afferents that project to those interneurons. It is unclear how the brain could learn such a complex model.

Regulator Models

Rather than trying to assign specific roles to each individual reflex or circuit, it may be more productive to look at the emergent properties of the complete spinal cord network. One approach is to ask what sorts of connections between afferents and efferents would be useful for solving typical problems in motor control. Given certain constraints, it is possible to apply an engineering tool for designing a linear quadratic regulator (LQR), which is essentially a matrix of excitatory and inhibitory gains between all possible pairs of input and output signals. The solution minimizes a cost function that reflects both the deviations from the desired state of the system and the expense of efforts to correct such deviations. When such a matrix was computed for maintaining stable standing posture in the hindlimb of a cat, the patterns of connections bore a striking resemblance to the patterns of connectivity in the major known interneuronal circuits listed above (Loeb et al. 1990; He et al. 1991). The matrix computed for a different mechanical state such as when freely moving through space would be substantially different, similar to the changes in reflex gains known to occur for such state changes. The methods used by engineers to compute such LQRs are unlikely to be employed by

the brain, but it is possible that they could be approximated by trial-and-error iteration over the lifetime of the animal.

While LQR analysis provides some insights into the general utility of the spinal cord for responding to perturbations, it does not provide a way to generate the desired states or trajectories in the first place. The general absence of direct cortical drive to the alpha motoneurons and the targeting of that drive onto the interneurons that mediate the reflexes suggest that the brain must plan simultaneously both the nominal behavior and desirable responses to anticipated perturbations (Loeb et al. 1999). The difficulty of computing such plans from inverse models suggests that they must be learned and stored as lookup tables and then replayed whenever the brain is called on to perform a familiar or at least similar task. Given the very large number of different interneuronal drives and synaptic gains in the spinal circuitry, is it feasible for solutions to be learned by trial-and-error exploration of this huge hyperspace?

Reasonably complete models of the classical spinal circuits that employ proprioceptive feedback (for the first five spinal circuits above, see Figs. 2 and 3) were constructed for an idealized 2DOF, 4-muscle wrist model (Raphael et al. 2010) and for a 2DOF, 6-muscle planar elbow-shoulder system (Tsianos et al. 2011). In both cases, simple trial-and-error adjustment from initially random states of the spinal cord resulted in kinematically successful and energetically efficient performance of a wide range of typical behaviors (resisting perturbations, rapid reaching to precise postures, compensation for viscous curl-fields, generating precise end-point forces). Success was attributed to the large number of “good-enough” solutions offered by the spinal circuitry, which seems to have little tendency to become entrapped in poor local minima. Solutions to one task provided useful starting points to learn new tasks, and sparse sets of such sequentially learned tasks could be interpolated to achieve intermediate behaviors despite the nonlinearity of the underlying neuromusculoskeletal system Tsianos et al. (in press). Somewhat disconcertingly, this implies that the internal representations of and strategies for a given motor behavior may differ

substantially among individuals. That would be consistent with the differences that emerge when physically “normal” individuals try to learn a new and unusual sport, but it makes it difficult to design and interpret experiments that usually require pooling data from many individuals.

Conclusions

The role of the spinal cord in learned sensorimotor behaviors remains contentious and may be shifting as animals evolve toward a wider repertoire of learned rather than instinctive behaviors. The propriospinal interneurons provide a case in point. In cats, these interneurons and their contribution to reaching movements are relatively easily demonstrated. In nonhuman primates, they are difficult to excite and, therefore, to find at all in anesthetized preparations (Alstermark et al. 2007). One possibility is that the resting bias of the spinal interneurons and perhaps other subcortical circuits may become hyperpolarized to suppress their reflexive responses until the cortex decides what combination of those reflexes will generate a more reasoned response. Another possibility is that the cortical systems that presumably subserve learned behaviors may simply overwhelm the other inputs to the spinal circuitry to take fairly direct control of the musculature, including the responses to perturbations (Kurtzer et al. 2008). Ignoring the phylogenetically old but sophisticated coordination provided by spinal interneurons might make sense if the brain needs to develop an internal model of the plant in order to compute motor programs *de novo*. Conversely, these circuits may be very useful if the brain must learn, store, and recall its repertoire without such online computation. Newly evolved musculoskeletal systems and functions such as dexterous manipulation of objects and vocalized speech may have no choice but to rely on newly evolved direct corticomotoneuronal projections, whether they are computing or recalling motor programs, but even these undergo substantial modulation by spinal circuits (Petersen et al. 2010).

Nevertheless, it is worth remembering that the first problem faced by a newborn brain is system

identification. It does not “know” that the external world and its own body exist, much less what effects its various output axons will have on that body. In the process of self-organizing that knowledge, the brain will discover and learn to cope with whatever musculoskeletal apparatus and local neural circuitry exist. Learning a new task must inevitably involve decisions about which components of the apparatus and the circuitry appear to be useful and which need to be ignored or suppressed. The challenge to the developing organism is to learn those tasks as quickly as possible, not to conform to abstract theories of how those tasks might be learned or performed.

Spinal cord stimulation

Definition

Spinal stimulation for Parkinson treatment is a neuromodulation procedure proposed as therapy for alleviating the motor symptoms of Parkinson's disease. It requires the epidural implant of bipolar electrodes in the dorsal portion of the spinal cord to deliver electrical pulses at specific frequencies.

Detailed Description

Spinal cord stimulation is a technique used for treating chronic pain conditions which are refractory to pharmacological therapies. In 2009 it was proposed that spinal cord stimulation could be used for treating the motor symptoms of Parkinson's disease (PD). PD is characterized by a lack of dopamine due to the death of the dopaminergic neurons of the substantia nigra. It interferes with the normal functioning of the corticobasal ganglia causing the classical symptoms of hypokinesia and rigidity, that is, slow movements and stiffness of the joints.

Patients and animal models of PD exhibit characteristic low-frequency, high-amplitude synchronous neural activity at the corticobasal ganglia loop. The rationale behind using spinal cord stimulation for PD was that high-frequency stimulation of spinal sensory afferents will convey to the supraspinal structures a signal capable of disrupting the low-frequency pathological rhythms, thus restoring normal functioning of the circuit.

The first experiments showed that dopamine-depleted mice showing strong akinesia would have their locomotion capability restored when receiving spinal cord stimulation. Further, rats with bilateral striatal 6-OHDA lesions, another model of PD, would exhibit the same effect. Electrophysiological recording in the mice showed that spinal cord stimulation caused dramatic changes in the synchrony pattern of the striatum and primary motor cortex, decreasing the low-frequency synchronization (<25 Hz) and increasing the synchronization at higher frequencies (>30 Hz).

The first report of spinal cord stimulation used in two PD patients failed to show any alleviation of motor symptoms. Four additional reports from different clinical groups over the world show that spinal cord stimulation used in PD patients who also suffer chronic pain, primary or secondary to PD, will experiment significant improvement of motor symptoms related to gate, locomotion speed, and posture.

Spindle Oscillations: Models

Alain Destexhe

Unit of Neuroscience Information and Complexity (UNIC), Paris-Saclay University, Institute of Neuroscience (NeuroPSI), Centre National de la Recherche Scientifique (CNRS), Gif-sur-Yvette, France

Definition

Sleep spindles appear during the early phases of sleep in all mammals. These 7–14 Hz oscillations are generated by the thalamus, but their triggering and large-scale synchrony depends on the cerebral cortex and thalamocortical interactions. Computational models have been designed to study how these oscillations are generated, what type of intrinsic currents and synaptic receptors is implicated, and how their synchrony is organized in the thalamocortical system.

Detailed Description

Introduction

The mammalian brain generates various types of slow oscillations during slow-wave sleep, such as spindle waves, delta oscillations, and slower oscillations (Steriade 2003). Spindle oscillations, which are mostly visible in the early stages of sleep (stage II in humans), are the best studied sleep oscillation because it is present in all mammals during sleep or anesthesia. Spindles are generated by thalamic circuits under physiological conditions, in contrast to delta and slow oscillations, for which cortical generators also exist. We focus here on sleep spindles, their genesis by thalamic networks, how these oscillations are distributed across the entire thalamocortical system.

Thalamic Pacemakers for Spindle Oscillations

Spindles are visible in the electroencephalogram (EEG), in which they consist of short 1–3 s

periods of 7–14 Hz oscillations, organized within a waxing-and-waning envelope, that recur periodically every 10–20 s. In cats and rodents, spindle waves of similar characteristics appear during slow-wave sleep and are typically more prominent at sleep onset. They are enhanced by some anesthetics, such as barbiturates, which, when administered at an appropriate dose, generate an EEG dominated by spindles.

The first indication that spindles could originate outside the cerebral cortex was from Bishop in 1936, who showed that rhythmical activity was suppressed in the cerebral cortex following destruction of its connections with the thalamus. In 1938, Bremer showed that rhythmical activity is still present in the white matter following destruction of the cortical mantle. Later, Adrian in 1941, and Morison and Bassett in 1945, observed that spindle oscillations persist in the thalamus upon removal of the cortex, providing firm experimental evidence that these oscillations originate in the thalamus. These experiments led to the development of the “thalamic pacemaker” hypothesis (Steriade and Deschênes 1984), according to which rhythmic activity is generated in the thalamus and communicated to the cortex, where it entrains cortical neurons and is responsible for the rhythmical activity observed in the EEG. The more recent discovery of spontaneously occurring spindles in ferret thalamic slices (von Krosigk et al. 1993) confirmed the thalamic pacemaker hypothesis. Furthermore, this *in vitro* model of spindle waves has made it possible to precisely characterize the ionic mechanisms and synaptic receptors involved in spindle oscillations.

Cellular Mechanisms of Spindle Oscillations

The first cellular mechanism to explain the genesis of spindle oscillations was proposed by Andersen and Eccles in 1962. From intracellular recordings from thalamocortical (TC) relay neurons during spindles, they reported that TC cells fired bursts of action potentials interleaved with inhibitory postsynaptic potentials (IPSPs). They

Spindle Oscillations: Models, Fig. 1 Spindle oscillations in thalamic circuits. (a) In vivo intracellular experiments realized in cats under barbiturate anesthesia, showing the activity of thalamocortical (TC) and thalamic reticular (RE) cells during spindle waves (modified from

Steriade and Deschênes 1984). (b) In vitro intracellular experiments realized in ferret visual thalamic slices, showing the activity of the same type of thalamic neurons during spindle waves (modified from von Krosigk et al. 1993)

suggested that TC cells fire in response to IPSPs (post-inhibitory rebound), which was later demonstrated to be a characteristic electrophysiological feature of thalamic cells by Jahnsen and Llinas. Andersen and Eccles suggested that the oscillations arose from the reciprocal interactions between TC cells and inhibitory local-circuit interneurons. This mechanism was later incorporated into a computational model that included a phenomenological description of the inhibitory rebound.

The mechanism proposed by Andersen and Eccles was seminal but was not entirely correct because reciprocal connections between TC cells and thalamic interneurons have never been observed in anatomical studies. It was later found by Scheibel and Scheibel (1966a, b, 1967) that the thalamic reticular (RE) nucleus, a sheet-like structure of inhibitory neurons surrounding the thalamus, could provide the inhibition of TC cells and that “TC-RE” loops could underlie recruitment phenomena and spindle oscillations. They predicted that the output of the RE nucleus should be inhibitory and that the inhibitory feedback from RE cells onto TC cells should be critical for the genesis of thalamic rhythmicity. This hypothesis was supported by the observation that the pattern of firing of RE neurons was tightly correlated with IPSPs in TC neurons.

The involvement of the thalamic RE nucleus in the generation of spindles was firmly established by a series of critical experiments by the group of Steriade in cats in vivo. The typical intracellular features of spindle oscillations in the two thalamic cell types are shown in Fig. 1a. By using intracellular or extracellular experiments, Steriade and collaborators have shown that, first, cortically projecting thalamic nuclei lose their ability to generate spindle oscillations if deprived of input from the RE nucleus (Steriade et al. 1985). Second, the isolated RE nucleus can itself generate rhythmicity in the spindle frequency range (Steriade et al. 1987).

Thus, three different mechanisms were proposed to explain thalamic rhythmicity: the “TC-interneuron” loops of Andersen and Eccles, the “TC-RE” loops of Scheibel and Scheibel, and the “RE pacemaker” hypothesis of Steriade (although Steriade’s work also demonstrated the importance of the cortex – see next section). The introduction of an in vitro model of spindle waves in young ferrets by McCormick’s group (Fig. 1b; von Krosigk et al. 1993) supported the second of these mechanisms. Slices of the visual thalamus that contain the dorsal (lateral geniculate nucleus or LGN) and reticular nuclei (perigeniculate nucleus or PGN), as well as the interconnections between them, generated spindles spontaneously,

confirming earlier experimental evidence for the genesis of spindles in the thalamus.

The great advantage of the *in vitro* preparation is that it allowed a detailed pharmacological investigation of the ionic currents and synaptic receptors underlying the spindle oscillations. The spindle waves disappeared after the connections between TC and RE cells were severed, consistent with the mechanism based on intrathalamic TC-RE loops proposed by Scheibel and Scheibel. This *in vitro* experiment also confirmed the observation that the input from RE neurons is necessary to generate spindles (Steriade et al. 1985). However, the RE nucleus maintained *in vitro* did not generate oscillations without connections from TC cells, in contrast with the observation of spindle rhythmicity in the isolated RE nucleus *in vivo* (Steriade et al. 1987).

Thus, *in vitro* experiments appear to support a mechanism by which oscillations are generated by the TC-RE loop, in contrast with the “RE pacemaker” hypothesis. Computational models are needed to investigate which of these mechanisms are plausible biophysically, as shown in the next section.

Models of Spindle Oscillations

Computational models investigated different cellular mechanisms of spindle oscillations, to attempt clarifying these contrasting experimental results. First, models investigated whether the RE nucleus is capable of displaying oscillations consistent with experiments. Models found that RE neurons interacting through GABAergic synapses can generate spindle rhythmicity (Wang and Rinzel 1993; Destexhe et al. 1994a; Bazhenov et al. 1999; reviewed in Destexhe and Sejnowski 2001, 2003) and proposed different mechanisms. GABAergic interactions between RE neurons can make them oscillate synchronously through mutual inhibitory-rebound interactions, either with slow GABAergic synapses (Wang and Rinzel 1993) or with fast (GABA_A receptor mediated) GABAergic synapses with extended connectivity (Destexhe et al. 1994a). Synchronized oscillations can also be generated from RE

neurons connected with depolarizing GABAergic synapses (Bazhenov et al. 1999). The presence of gap junctions in the reticular nucleus (Landisman et al. 2002) was also incorporated in models (Fuentelba et al. 2004) and reinforced its propensity to oscillate in the spindle frequency range. Thus, models suggest that the intrinsic properties of thalamic RE neurons, combined with their synaptic or electrical interactions, support the RE pacemaker hypothesis.

Second, models also investigated the TC-RE loop hypothesis for spindle generation (Destexhe et al. 1996; Golomb et al. 1996). This TC-RE loop model is shown in Fig. 2d. Neurons were modeled using Hodgkin-Huxley (1952)-type representations of Na⁺, K⁺, and Ca²⁺ voltage-dependent currents, which were based on voltage-clamp data on thalamic neurons (see details in Destexhe et al. 1996). These models reproduced the most salient intrinsic properties of thalamic neurons, such as the production of bursts of action potentials (Fig. 2b). Synaptic interactions were modeled using conductance-based kinetic models (Kinetic Models of Postsynaptic Currents) which were used to simulate the main receptor types (AMPA, GABA_A, and GABA_B) identified in thalamic circuits (Fig. 2b, right). Under these conditions, the circuit generated 7–14 Hz spindle oscillations with the typical features identified intracellularly in the different thalamic neuron types. The model reproduced the typical mirror image between TC and RE cells during spindles, as well as the phase relations between cells (see Fig. 2d). In particular, TC cells produced bursts once every 2–3 cycles, a feature consistently observed experimentally (compare with Fig. 2c). More irregular behavior, similar to the experiments, was obtained in larger networks (Fig. 2e) or in the presence of the cortex (see below). The oscillations also showed the typical waxing-and-waning envelope of spindles; this property was due in the model to Ca²⁺-mediated slow regulation of the I_h current (Destexhe et al. 1993), a prediction that was later verified experimentally (Lüthi and McCormick 1998).

Thus, models show that taking into account the complex bursting properties of thalamic neurons, combined with their interactions through

well-defined types of synaptic receptors, can account for both RE pacemaker oscillations and spindle oscillations arising from TC-RE loops without assuming pacemaker activity in the RE nucleus. How to resolve such an apparent inconsistency? This question was addressed by a computational model of the RE nucleus which took into account the action of neuromodulators (such as noradrenaline) in depolarizing RE cells. This model produced

oscillations only when a sufficient level of neuromodulator was present (Destexhe et al. 1994b). The difference between *in vivo* and *in vitro* preparations may therefore be explained by the limited connectivity between the RE neurons in the slice and/or by the fact that slices lack the necessary level of neuromodulation to maintain isolated RE oscillations (Destexhe et al. 1994b). The main prediction from this model is that

(d) Large-scale synchrony obtained in a thalamocortical model (modified from Destexhe et al. 1998)

applying neuromodulators to slices of the RE nucleus should induce oscillations similar to those observed in vivo. This prediction still awaits to be tested.

Dialogue Between the Thalamus and Cortex: Emergence of Large-Scale Synchrony

The large-scale properties of initiation and distribution of spindle oscillations were investigated more recently by using multiple recordings in vivo and in vitro (Fig. 3a, c). Spindle oscillations in vitro show traveling wave patterns, with the oscillation typically starting on one side of the slice and propagating to the other side, at a constant propagation velocity (Fig. 3a). In contrast to thalamic slices, the intact thalamocortical system in vivo does not display such clear-cut propagation, but spindle oscillations are remarkably synchronized over extended thalamic regions and show very limited traveling wave activity (Fig. 3c), in agreement with early observations. Moreover, a study by Contreras et al. in 1996 showed that large-scale synchrony was lost when the cortex was removed, suggesting that although the oscillation is generated by the thalamus, its synchrony depends on the cortex. However, cutting intracortical connections has no effect on large-scale synchrony, so cortical connections are not responsible for organizing the synchrony of sleep spindles.

Computational models were designed to explore mechanisms to explain the large-scale synchrony of sleep spindles, as shown in detail in another chapter (► [“Corticothalamic Feedback: Large-Scale Synchrony”](#)). Models first simulated the propagating properties found in slices (Fig. 3b). These models assumed a topographic connectivity between TC and RE layers and could generate traveling spindle waves consistent with in vitro data. Second, a thalamocortical model (Destexhe et al. 1998) simulated large networks with bidirectional interactions between cortex and thalamic layers and showed that all experiments could be reproduced under one assumption: that the cortex recruited TC cells primarily through inhibition. This “inhibitory dominant” cortical feedback to

the thalamus is consistently observed experimentally and can explain large-scale synchrony by mutual recruitment of thalamic and cortical networks (Fig. 3d). The same mechanism can also explain the genesis of absence type of epileptic seizures when the excitability of cortical neurons is too high. These points were developed in more detail in another chapter (► [“Slow Oscillations and Epilepsy: Network Models”](#)). The concept of cortical control of thalamic spindle oscillations can be generalized to other oscillation types, and it was proposed by Steriade that the slow oscillation organizes spindle, delta oscillations and more complex patterns such as K-complexes (Steriade 2003).

Definition

Whole-brain computational models of the spontaneous dynamics of coupled brain areas. These models are useful to investigate the origin of ongoing fluctuations observed in brain activity during rest and their correlation structure.

Detailed Description

A growing body of neuroimaging research has revealed that during rest the brain exhibits spontaneous fluctuations in neural activity. These fluctuations emerge spontaneously during quiet wakeful rest and vanish either when triggered by

a task or when falling asleep. This type of spontaneous activity has been mostly detected in the blood-oxygen level-dependent (BOLD) signal using functional magnetic resonance imaging (fMRI) (Biswal et al. 1995). Explorations into the spatial organization of these spontaneous activations have revealed the existence of correlated activity (or *functional connectivity*) between spatially segregated brain areas. These functional connections appear closely related to the underlying map of white matter neuroanatomical connections. However, to understand spontaneous activity from a mechanistic perspective, anatomical information is not sufficient, and it is important to consider the way brain areas interact when they are in the spontaneous state. This is where bottom-up computational models of spontaneous activity come forward, since they allow testing potential theoretical scenarios by comparing the numerical simulation with real resting-state signals in health and disease (Ritter et al. 2013; Deco et al. 2013a; Cabral et al. 2014). In general, models of spontaneous activity consist in a whole-brain network model, where the nodes represent brain areas and the links represent the structural connections between them. Differences between models consist essentially on the equations used to describe the dynamics at the node level, i.e., the behavior of a brain area in the spontaneous state, and the way brain areas interact.

Models of Spontaneous Activity

Anatomical Connectivity

One main component of models of spontaneous activity is the anatomical connectivity matrix, which expresses the coupling weights between brain areas. Typically, these coupling weights are scaled in proportion to the number of white matter fiber tracts connecting each pair of brain areas. The first models of spontaneous activity (Honey et al. 2007; Ghosh et al. 2008; Deco et al. 2009) have used the anatomical connectivity between 38 brain areas from one hemisphere of the macaque brain (Kötter 2004). More recent models (Honey et al. 2009; Cabral et al. 2011; Deco and

Jirsa 2012; Deco et al. 2013b) have used the human anatomical connectome derived in vivo from diffusion MRI between 66 brain areas covering the whole cortical surface (Hagmann et al. 2008) or 90 brain areas defined according to the AAL template (Cabral et al. 2012). In some models, the structural distance between brain areas is also taken into account, as it induces time-delayed interactions between brain areas (Ghosh et al. 2008; Deco et al. 2009; Cabral et al. 2011, 2012) (Fig. 1).

Local Node Model

Another main component of the models is the type of dynamics assumed at the node level, i.e., the intrinsic behavior of brain areas when they are in the spontaneous state. Assuming that each brain area consists in a system of densely interconnected neurons, the population dynamics can be represented, in a reduced manner, by a small set of differential equations. Existing models of spontaneous activity represent the dynamics of a local brain area in the following ways:

- Conductance-based biophysical neural mass model (Honey et al. 2007, 2009)
- Fitzhugh–Nagumo Model neural mass model (Ghosh et al. 2008).
- Wilson-Cowan Model of excitatory and inhibitory neural pools (Deco et al. 2009).
- Coupled oscillator using an extended version of the Kuramoto model (Cabral et al. 2011).
- Node model in an asynchronous state (Cabral et al. 2012).
- Attractor network of spiking neurons (Deco and Jirsa 2012)
- Dynamic mean field model (Deco et al. 2013b)

Depending on the models, coupled brain areas may display different dynamical regimes, namely, a fixed-point attractor, a limit-cycle attractor, or a chaotic attractor. In the first case, all neurons in a brain area fire irregularly, and the system tends to a stable asynchronous state. In this case, oscillations are damped and manifest as resonances in the network response (Ghosh et al. 2008; Deco and Jirsa 2012; Deco et al. 2013b; Cabral et al.

Spontaneous Activity, Models of, Fig. 1 Anatomical network. Anatomical connectivity between with 66 brain areas derived using DSI averaged over five healthy subjects (Hagmann et al. 2008). (Top-left) The coupling weights are proportional to the number of tracts detected. Weights were normalized so that $0 \leq C_{np} \leq 1$. White = no

connection. (Bottom-left) Distance between regions given as the average length of the fibers connecting a pair of regions. (Right) Schematic representation of the anatomical network, where regions (red spheres) are placed at their center of gravity and the link's thickness is proportional to the number of fiber tracts detected in each connection

2012). On the other hand, when the neurons in a brain area fire synchronously with rhythmic periodicity due to recurrent excitation and inhibition, then neural populations display self-sustained oscillations, and the dynamics is approximated to a limit-cycle attractor (Deco et al. 2009; Cabral et al. 2011). Finally, when the local network exhibits intrinsic instabilities where nonperiodic intermittent oscillations occur due to nonlinear interactions between neurons, then a chaotic dynamics is instantiated (Honey et al. 2007, 2009). Although there is a qualitative difference between models, all scenarios are plausible in the light of the current knowledge in spontaneous neural dynamics.

Systems of Coupled Brain Areas

Coupling local node models according to the whole-brain anatomical network structure, it is possible to simulate the behavior of coupled brain areas at a global scale. In the models, each brain area receives excitatory input from anatomically connected brain areas. In general, the main parameter of the models is the global coupling weight, which scales the anatomical connectivity matrix. When the distance between brain areas is considered, a finite (typically homogeneous) transmission speed is assumed resulting in time-delayed inputs (Ghosh et al. 2008; Deco et al. 2009; Cabral et al. 2011). In addition, some models include an external noisy input (Ghosh

et al. 2008; Deco et al. 2009; Deco and Jirsa 2012; Cabral et al. 2012). Depending on the model, delays and/or noise may – or not – play a role in shaping the dynamics of the brain at rest.

Simulated BOLD Functional Connectivity

To compare the simulated neural activity with data from resting-state fMRI functional connectivity, it is necessary to estimate the BOLD signal changes associated with the simulated signals. Existing models of resting-state activity have used the Balloon-Windkessel hemodynamic model (Friston et al. 2003) to estimate the BOLD signal from simulations. Subsequently, the simulated spontaneous functional connectivity is computed by calculating the correlation matrix between the simulated BOLD signals in all brain areas. For a range of parameters (generally the global coupling weight but also the transmission speed and the noise level when these are considered), the system displays slow BOLD signal fluctuations with a correlation structure that fairly approximates the empirical BOLD functional connectivity. Importantly, for all models, the optimal fit with the empirical data is found for a set of parameters where the system operates at the edge of an instability, i.e., at the critical point of a bifurcation. This intrinsic instability of the system leads to the amplification of the underlying anatomical structure. In other words, at that critical bifurcation point, the global network dynamics reveals correlation patterns that are spatially shaped by the underlying anatomical structure, leading to an optimal fit with the empirical BOLD functional connectivity.

Discussion and Future Directions

Existing models of spontaneous activity point to the direction that the brain during rest reflects an intrinsically unstable regime, where a repertoire of different functional network configurations is temporarily activated. However, the dynamics occurring at time scales faster than the hemodynamic response, as well as the nonstationarity of resting-state functional connectivity, has not been adequately addressed in computational models.

To provide a global picture of the dynamics occurring in the brain at rest, existing and future models need to go beyond reproducing fMRI functional connectivity matrices and explore the non-stationary connectivity dynamics, as well as the faster oscillatory dimension, revealed with other neuroimaging modalities, such as EEG, intracranial recordings, and MEG. Going beyond the BOLD signal, these methods provide pictures of resting-state dynamics from new perspectives, which must be taken into account in future models to deepen our understanding on resting-state activity.

Stability and Homeostasis in Small Network Central Pattern Generators

Jorge Golowasch
 Federated Department of Biological Sciences,
 New Jersey Institute of Technology/Rutgers
 University, Newark, NJ, USA

Synopsis

All animals contain circuits in their central nervous system that produce rhythmic activity. The circuits, often referred to as central pattern generators (CPGs), typically underlie vital activities or behaviors, such as locomotion, respiration, heartbeat, digestion, circadian activity, etc. (Marder

et al. 2005). By the very nature of these behaviors, they require a certain degree of stability of the individual parameters or features that characterize the activity to ensure the survival of the individual. In patterned activity, a key activity feature is the relative timing of activation (phase) of different components of the network. On the other hand, the nervous system is best known for its plasticity and capacity to change in response to many types of inputs. Thus, how stability of activity is ensured is the subject of intense research. In order to attain a stable state, the neurons in these circuits need mechanisms that monitor the state of the system to homeostatically adjust parameters that bring the system to within operational limits. Here, we discuss conditions and likely mechanisms that participate in this process. It is important to note that this field is, as of early 2014, in its early stages of development and much remains to be discovered and understood.

Central pattern generators (CPGs). Networks (or parts of networks) that autonomously produce patterned activity, without requiring timing cues from external sources to the network.

Model Systems

Species with anatomically simple nervous systems that include small CPG-containing networks are among the ones that offer the best opportunities for understanding the basic mechanisms in operation. Such species (and small neuronal networks) include crabs and lobsters (pyloric, gastric, and cardiac networks), leech (heartbeat network), nudibranchs such as *Tritonia* and *Clione* (swimming network), snails such as *Aplysia* and *Lymnaea* (feeding network), etc. (Marder et al. 2005). The simplicity of the networks involved lies primarily in their low number of neurons, of which the majority are identified, large, and often found in low copy number, thus ensuring unequivocal identification of the component neurons involved in the CPG. Modern molecular and optogenetic methods are bringing us closer to the possibility of manipulating large numbers of identified neurons in more complex networks, but identification challenges remain a problem (Carroll et al. 2013). When working with model

systems with large numbers of neurons, great care needs to be exercised to ensure that a subclass within a large neuronal class does not express a gene or protein different enough to determine a distinct function, while expressing the marker that characterizes the broader class. If this latter marker is used to identify the class, one may be wrong in assuming that all cells belong to the same class.

What Is Stable?

In principle, any feature by which network activity may be characterized could be a target for homeostatic mechanisms that stabilize activity. Here, we will focus on network properties primarily but will describe some cases in which the properties of individual cells of small networks are found to be conserved. Additionally, two very different types of stability, likely to depend on distinct types of homeostatic mechanisms, are observed: one is the consistency of activity patterns over many individuals, which we will refer to as *population stability*. Another is the consistency of activity patterns over time within an individual, which we will refer to as *individual stability*.

In pattern generators, it is frequently the case that the phases of activities of the neurons in the network need to be stabilized. This ensures that different segments in the body, for example, bend in the correct sequence to ensure propulsion when swimming (Varkonyi et al. 2008) and that the contraction of agonistic and antagonistic muscle occurs in the appropriate temporal relationship to enable walking instead of hopping or trotting (Kiehn 2011) or to enable the correct sequence of inspiratory and expiratory muscle contractions in the respiratory system (Carroll et al. 2013). In the pyloric network of crustaceans, several neuronal types fire in a specific order and drive the contractions of the about 40 muscles found on the pyloric sac. The phase at which each of the participating neurons starts and ends their bursts of activity is extremely well conserved across individuals (Bucher et al. 2005; Goillard et al. 2009). A similar example of stability has been

observed in the leech heart network, a network of neurons spanning several ganglia along the length of the animal, whose relative order of activity is essential to ensure the proper order of muscle contraction of the heart muscles that spans the length of the animal (Roffman et al. 2012). Thus, it can probably be safely concluded that phase control and stabilization under certain conditions is a general requirement for pattern generating networks.

Phase. A fraction that an event in a pattern takes relative to the duration of one cycle. Thus, the fraction of time during which a neuron is active (e.g., spiking) is its active phase; the onset phase is the point in a cycle when activity begins, etc.

Another feature of small pattern generating networks that has been found to be conserved in some systems is the ability to restore the pattern to a state that is similar to the natural, unperturbed state after it is disrupted by external perturbations. This individual stability property has been observed in a number of different systems and in response to different perturbations, including stroke, spinal cord injury, deafferentation, temperature changes, etc. Although this type of feature has been widely studied at the level of individual synapses or intrinsic properties (and termed homeostatic plasticity in general (Williams et al. 2013)), we will discuss some of the cases that are relevant to small, pattern generating networks in some detail below.

The requirement to stabilize phase of activity is challenged by two different sources of variability in the system. One is the varying nature of the inputs that the nervous system receives and to which it must respond adaptively in a moment-by-moment basis to maintain phase constant. This is, therefore, an issue that applies at the level of individuals and will here be referred to as *individual stability*. Another challenge that has been observed in uniquely identified neurons across animals is the high degrees of variability with which both synaptic and intrinsic ionic currents (which generate the activity of the CPGs) are expressed while maintaining the activity strikingly similar across the population. This issue will here be referred to as *population stability*.

Population Stability

The best known examples of population stability are found in the pyloric network activity of crustaceans, namely, lobsters and crabs, and the heartbeat activity of leeches. When recorded over a large population of unrelated animals, the activity of pyloric network neurons shows large variability in frequency, yet remarkable phase constancy, with each neuron activating and terminating its bursts of activity at a phase that is nearly completely independent of frequency (Bucher et al. 2005; Goaillard et al. 2009). A very similar phenomenon occurs in the network that controls the leech heartbeat (Norris et al. 2006). Phase constancy across individuals is also observed in lampreys and fish, where very precise phase shifts in the contraction of adjacent body segments during swimming are highly conserved across animals and independent of frequency (Lansner et al. 1998). The advantage in studying crustaceans and leeches is that the neurons involved in the generation of the rhythmic pattern are so few that we can be certain to identify each player. Moreover, in each one of these uniquely identified neurons, it has been possible to measure the amplitudes and properties of each of the ionic currents they express. The interplay of synaptic and intrinsic ionic currents is what determines the excitability and overall electric properties of the neurons in a network. Thus, it came as a surprise when a few years ago reports began to appear that showed that these currents are expressed at severalfold different levels between animals whose phase relationships were almost identical (Liu et al. 1998; Schulz et al. 2006; Goaillard et al. 2009; Roffman et al. 2012). Two alternatives can be envisaged to explain such independence of a crucial functional trait (phase) from the amplitudes, and probably also other parameters, of the currents that generate that activity: one is that the variable currents do not play a significant role in determining phase relationships. That is unlikely to be the case since even the synaptic currents that most influence phasing are highly variable (Goaillard et al. 2009; Roffman et al. 2012). The other alternative is that somehow the ionic currents involved compensate for each other in their effects on phase and

other activity features. What compensations are likely to be observed? An intuitively easy relationship to understand is the amplitude of an inward and an outward current. They can in principle be functional antagonists even though their specific kinetic and voltage-dependent properties will determine how complementary they actually are. MacLean et al. showed that this was the case, for example, between the hyperpolarization-activated inward current (I_h) and the transient K^+ current (I_A) in lobster neurons that lead to the constancy of delay to first spike among neurons with different but compensating levels of these currents (MacLean et al. 2003, 2005).

The phenomenon of currents compensating for each other to stabilize an activity feature translates at the population level into the observation of the correlated expression of such ionic currents or conductances between individuals. In other words, correlated currents are currents whose amplitudes track each other, either positively (one grows proportionally to the growth of another) or negatively. This has now been shown in several cases, both in the small networks discussed here (Khorkova and Golowasch 2007; Schulz et al. 2007; Goaillard et al. 2009; Zhao and Golowasch 2012) and in vertebrate neurons from much more complex networks (Amendola et al. 2012; Unal et al. 2012). A growing body of both experimental and theoretical evidence indicates that the correlated expression of different ionic currents, including voltage-gated conductances as well as synaptic conductances, may be required to ensure stability of function (MacLean et al. 2003; Schulz et al. 2006, 2007; Khorkova and Golowasch 2007; Hudson and Prinz 2010; Temporal et al. 2012). In the pyloric network, for example, it has been shown that loss of rhythmic activity is accompanied by the loss of the correlated expression of certain voltage-gated currents, such as I_h and the high-threshold K^+ current, I_{HTK} , in one cell type (Khorkova and Golowasch 2007; Temporal et al. 2012). It has also been observed that a number of activity properties in this network are correlated with more than one conductance (Goaillard et al. 2009; Zhao and Golowasch 2012). This indicates that the maintenance of constant phase relationships in a population of

animals can be achieved in principle if neurons simultaneously control multiple conductances in a coordinated manner.

A similar situation can be observed in the leech heartbeat system. Here, we observe phase relationships between adjacent segments of the animal that are highly preserved across individuals (Norris et al. 2006). Underlying this, we find a wide range of synaptic conductances (Norris et al. 2011; Roffman et al. 2012). Thus, the question of how phases are maintained when synaptic currents are highly variable comes up here again. It had been hypothesized that the relative strengths of the synaptic inputs that the heart motor neurons receive from its presynaptic interneurons would determine the stable output of the network (Norris et al. 2007). However, extensive testing of this hypothesis did not clearly confirm that prediction (Norris et al. 2011), even though recent theoretical work indicates that synaptic conductance correlations are to be expected (Lamb and Calabrese 2013). Instead, it is now suggested that a more complex set of compensatory (or tuning) interactions between intrinsic and synaptic conductances may be responsible for the consistent phase relationships of the motor output (Norris et al. 2011).

Mechanisms

How can ionic currents be linked in a way that correlations appear at the population level? Several possibilities can be envisaged: (1) sets of ion channels are transcriptionally linked by common transcription regulation factors; (2) co-expression of, or co-assembly into, ribosomes (or ribosome granules), of sets of ion channel mRNAs; and (3) shared posttranslational modification or co-localization of distinct ion channels in macromolecular assemblies. A very interesting recent theoretical study showed that ionic conductance correlations will result when a set of correlated ionic currents are all regulated in an activity-dependent manner, with the actual relationship that describes the coupling determined by the relative rates of regulation (O'Leary et al. 2013). Thus, if a target activity trait is regulated in an activity-dependent manner, coupled conductances across a population of cells will naturally arise

from a set of random initial conditions. Furthermore, the relationships that characterize this coupling can be linear (O'Leary et al. 2013), which is fully consistent with a growing number of observations of such relationships, both theoretical and experimental (Burdakov 2005; Schulz et al. 2006, 2007; Khorkova and Golowasch 2007; Ball et al. 2010; Temporal et al. 2012).

Individual Stability

At the individual level, two distinct types of stabilization of phase relationships in CPGs have been described. One is the immediate regulation of phase in response to changing inputs to the CPG and to which it responds quickly to maintain phase constant. Another is the much slower response to drastic perturbation that may be described as recovery of function.

Phase Control

In many systems, phase maintenance depends on mechanisms operating at the level of the synaptic connectivity (circuitry) of the networks. Thus, different synaptic strengths along a gradient of body segments (Williams 1992) or the strength or number of excitatory or inhibitory connections between segments (Skinner and Mulloney 1998) can account for the different types of phase relationships in multisegmented animals (fish, lampreys, etc.). A different mechanism was proposed for the phase maintenance in networks consisting of follower neurons inhibited by oscillating or pacemaker neurons, a case commonly found among CPGs (Manor et al. 2003). Using computational and analytical tools the authors showed that short-term synaptic depression of the inhibitory synapse can create phase maintenance. The idea behind this mechanism is that synaptic depression is dependent on frequency: the longer the synapse is active (such as when rhythm frequency is low), the more it depresses and thus the less effective the synapse becomes. With appropriate parameters, the synaptic delay can be nearly proportional to the change in cycle frequency and thus phase be well maintained (Manor et al. 2003).

A related study shows that the interaction of synaptic depression and the properties of inactivating K^+ currents could further contribute to phase constancy (Greenberg and Manor 2005). These mechanisms act with time constants close to the time constants of synaptic depression and current inactivation, both of which are close to the cycling frequencies of networks. They therefore function to maintain phase constancy at short time scales that are commensurate with the frequency of the network patterns.

Recovery of Function

Several small neuronal networks exhibit robust but much slower compensatory responses to perturbations than those described in the previous section. The responses lead to recovery of function and can bring the entire network back to a state similar to that prior to receiving the perturbation. In the mollusk *Tritonia diomedea*, for example, the escape swimming pattern can be characterized by a series of body flexions induced by sensory stimuli. A fictive motor pattern that underlies this behavior can also be elicited in preparations of the isolated brain in vitro (Katz 2009). When the connections between two of the key components of the swimming CPG are broken, the entire swimming pattern is disrupted and escape responses can no longer be elicited. However, within 1 day after the lesion, the escape responses are restored to levels almost indistinguishable from the control without reconnection of the severed connection (Sakurai and Katz 2009). This recovery of function is driven by a reconfiguration of the dendritic tree whereby one neuropilar region of the cell takes over the function of the dominant one located in the severed region. What molecular mechanism accounts for this is unknown.

In the pyloric network of crustaceans, we observe a similar phenomenon. The pyloric network resides in the stomatogastric ganglion (STG), and its activity is generated in a manner that depends on the uninterrupted release of neuromodulators from projecting neurons whose cell bodies are found in ganglia adjacent to the STG (Selverston and Moulins 1986). When these

axons are severed or their action potential transmission is blocked (a process described as decentralization), pyloric activity rapidly ceases. However, within several hours to a few days, depending on the species, certain aspects of the pyloric rhythm (notably the phase relationships between the members of the network) return to control levels (Thoby-Brisson and Simmers 1998; Luther et al. 2003). What is particularly interesting about this recovery is that the phase relationships in the preparations whose pyloric rhythm has fully recovered are nearly indistinguishable from those observed before decentralization even though the frequency of the rhythm is typically slower. This is reminiscent of the population stability features observed in intact preparations in which phase relationships are tightly maintained but frequency is much more variable (Bucher et al. 2005; Goaillard et al. 2009). Before the recovery has reached its near control levels, however, the phase relationships as well as the frequency are significantly different from the final stable state (Luther et al. 2003). At the same time, ionic conductance amplitudes and their correlation levels change dramatically (Khorkova and Golowasch 2007; Temporal et al. 2012). One possible explanation for this is that whatever mechanisms that keep current amplitudes tied to one another under control conditions (during which neuromodulator levels are relatively high) are released. With this, amplitudes and correlations become free to change within a wide parameter space, perhaps different from the one normally visited by the cells under the normal neuromodulatory state. This may be necessary to find a new set of values for each of the conductances that can sustain stable activity again but now in the continuous absence of neuromodulators. Such robustness of the activity of this network is further revealed in response to temperature changes. Temperature shifts induce large and significant changes in pyloric rhythm frequency, but the network remains capable of maintaining a remarkably stable set of phase relationships even when the temperature changes (and consequently, the frequency) are made quite rapidly (minutes) and over a wide range (Tang et al. 2010). Thus, here again we find that the relative timing of activity between

the component neurons is a crucial parameter that is conserved or stabilized over very different conditions.

What mechanisms may be responsible for these effects? Different mechanisms of homeostatic regulation are found, even though a full picture has not yet emerged. Synaptic plasticity is clearly involved in several of these cases. For instance, the stabilization of phase relationships within the pyloric network when the temperature of the network is changed is accompanied by synaptic strength changes among several of the synaptic connections, as well as intrinsic ionic current modifications (Tang et al. 2010). The recovery of the pyloric rhythm after decentralization also appears to involve synaptic strength changes as well as changes to voltage-gated ionic conductances (Thoby-Brisson and Simmers 2002; Khorkova and Golowasch 2007), perhaps via changes in intracellular calcium regulation mechanisms (Zhang and Golowasch 2011). Interestingly, changes induced by decentralization on the correlation between ionic currents have also been observed, indicating that conductance correlations are somehow under neuromodulatory control (Khorkova and Golowasch 2007).

Definition

An adaptation of the state-space paradigm to the analysis of neuroscience data in which the observation model is either a point process or a time series of binary observations and the state model is typically a linear Gaussian process. The paradigm has been applied to a number of problems including neural spike train decoding, analysis of receptive field dynamics, analyses of learning, neural prosthetic control, and control of brain states under anesthesia.

The state-space paradigm for analyses of point processes and time series of discrete binary observations has been developed for the analysis of neural spike train and behavioral data (Brown et al. 1998; Smith and Brown 2003). The state-space point process (SSPP) paradigm has two standard components. The state equation defines the system dynamics. The observation equation

defines how the system is measured. For the SSPP system the observations can be point processes or time series of discrete binary responses. Point processes are binary (0–1) events defined in continuous time. They are an ideal framework for analyzing series of neuronal action potentials where the binary events are defined as 1 if there is an action potential or spike and 0 otherwise. Data in behavioral studies commonly consist of time series of binary responses such as in a learning experiment where 1 is given for a correct response and 0 is given for an incorrect response. In system neuroscience experiments, the state equation defines the signal, stimulus, or brain state that is being represented by the neural activity or the behavior.

Detailed Description

Derivation of the State-Space Point Process Filter Algorithm

The use of the state-space paradigm to analyze neural spiking activity was introduced by Brown and colleagues, using an inhomogeneous Poisson observation model and a linear Gaussian state model to study the decoding of position from ensemble neural spiking activity in rodents (Brown et al. 1998; see ► [“Neural Coding”](#); ► [“Population Encoding/Decoding”](#)). The objective of the state-space analysis is to estimate the state at time t , given the data, up through time t (Brown et al. 1998; Smith and Brown 2003). The solution to this prediction problem is defined recursively by the associated Bayes’ rule Chapman-Kolmogorov (BCK) system (see ► [“Bayesian Approaches in Computational Neuroscience: Overview”](#)). Bayes’ rule defines the posterior density of the state at time t given all of the observations from the start of the experiment up through time c . The Chapman-Kolmogorov, or one-step prediction equation, defines the probability density of the state at time t given the observations up through time $t - 1$ (Chen et al. 2010). This probability density is computed by integrating the product of the posterior density at time $t - 1$ and the state model that is typically Markov and defines the

probability density of the states at time t given the state at time $t - 1$. Brown and colleagues showed that the state estimation from point process observations could be efficiently conducted by deriving a nonlinear recursive filter (NRF) algorithm to solve the associated BCK system (Brown et al. 1998; see ► [“Digital Filtering”](#)). The derivation used two approximations to derive the algorithm. First, it approximated continuous time as discrete time in small intervals and assumed a single (0 or 1) Poisson observation in each interval. Second, the NRF algorithm is derived by using a Gaussian approximation to integrate the BCK system and a second Gaussian approximation to compute the *maximum-a-posteriori* state estimate and its covariance matrix. The NRF algorithm becomes the Kalman filter algorithm when the observation equation is a linear function of the state and the observation noise is Gaussian and additive.

Extensions of the State-Space Point Process Theory

Brown and colleagues demonstrated that a point process adaptive filter algorithm is a special case of the NRF algorithm (Brown et al. 2001). They next developed an expectation-maximization algorithm to conduct simultaneous state and static model parameter estimation from general point process (non-Poisson) or time series of binary observations (Smith and Brown 2003; see ► [“Generalized Linear Models for Point Process Analyses of Neural Spiking Activity”](#)) and an augmented adaptive filter algorithm to conduct simultaneous state and dynamic model parameter estimation (Eden et al. 2004). The general point process paradigm improved the previously developed decoding algorithms (Brown et al. 1998) and defined explicitly the relationship between decoding the representation of a signal in an ensemble of neurons and measuring dynamically the mutual information between the signal and the ensemble spiking activity (Barbieri et al. 2004; see ► [“Information Theory: Overview”](#)). The SSPP paradigm also provides a principled approach to analyzing binary data series recorded

in learning experiments and explicit criteria to define when learning occurs (Wirth et al. 2003; Smith et al. 2004).

Brown and colleagues extended the SSPP algorithms to derive the exact state estimation algorithms for point processes using sequential Monte Carlo methods (Ergun et al. 2007), conduct state estimation from simultaneously observed point process and binary and continuous observations, (Prerau et al. 2008, 2009; Coleman et al. 2010) and implement deterministic and stochastic control systems (Ching et al. 2013; Shanechi et al. 2013a, b, c). Extensions of the state-space point process framework include the use of Markov chain Monte Carlo computations (Ahmadian et al. 2011; Yuan et al. 2012) and the analysis of interactions among simultaneously recorded neural spike trains using information geometry concepts (Shimazaki et al. 2012; see ► [“Information Geometry as Applied to Neural Spike Data”](#)).

Applications of the State-Space Point Process Paradigm

The first application of the SSPP was as a new paradigm to decode spatial information from ensembles of the hippocampal place cell neurons (Brown et al. 1998; see ► [“Efficient Population Coding”](#); ► [“Estimation of Neuronal Firing Rate”](#)). This analysis showed how ensembles of the hippocampal neurons maintained precise, dynamic representations of a rat’s spatial location during foraging (Brown et al. 1998). The SSPP algorithms outperformed by an order of magnitude ad hoc algorithms in decoding spatial information from ensembles of the hippocampal neurons (Brown et al. 1998). The adaptive filter algorithm special case of the SSPP algorithm was used to study receptive field plasticity in the hippocampal neurons (Brown et al. 2001; Frank et al. 2004). An SSPP analysis showed that rodent hippocampal neurons can form new spatial receptive fields in 5–6 min (Frank et al. 2004) and that in monkeys, hippocampal neuronal activity changes are tightly coupled to the acquisition of newly learned behaviors (Wirth et al. 2003). The SSPP algorithm applied to binary data established a new

paradigm for dynamic analysis of behavior in learning experiments (Wirth et al. 2003; Smith et al. 2004; Prerau et al. 2008; Prerau et al. 2009; see ► [“Behavioural Analysis, Bayesian”](#)).

The SSPP algorithm accurately decoded motor cortex representations of hand positions (Truccolo et al. 2005). SSPP algorithms have been used to track heart rate variability, (Barbieri and Brown 2006) to track brain states under general anesthesia, (Chemali et al. 2013) and to precisely define anesthesia-induced loss and recovery of consciousness (Purdon et al. 2013; Wong et al. 2014). The SSPP algorithms established that during motor learning different groups of neurons can represent different movement components (Shanechi et al. 2012). SSPP algorithms have been used to implement stochastic and deterministic control paradigms: linear-quadratic regulatory algorithms for motor neural prostheses (Shanechi et al. 2013a, b; see ► [“Brain-Machine Interface: Overview”](#)) and proportional-integral, (Ching et al. 2013) linear-quadratic regulator and model predictive control algorithms (Shanechi et al. 2013c) to precisely maintain the brain in a medically induced coma. For motor prosthetic control, Carmena and colleagues recently showed that the SSPP paradigm outperforms by 30% the widely used Kalman filter control paradigm (Shanechi et al. 2013d; see ► [“Brain-Machine Interface: Overview”](#)).

Statistical Analysis of Neuroimaging Data

Tohru Ozaki

Institute of Statistical Mathematics, Tokyo, Japan

Definition

The main goal of “statistical analysis of neuroimaging data” is to use statistical methods to extract useful neuroscientific information, from neuroimaging data such as fMRI, EEG, and MEG, which are derived from measurement of the dynamics of electrical and magnetic activity generated from the neural and vascular activities inside the live brain.

Detailed Description

A typical example is the statistical analysis of fMRI data, where the activation and deactivation of voxels (as measured by the BOLD signal) in response to some specific task of interest may be elucidated in a map called the activation map. Similarly for EEG/MEG data analysis, one of the main interests of statistical analysis is to estimate the activation of areas in response to specific stimuli to the live brain. It provides the basis for further elaborate statistical analysis, such as the analysis of dynamic causalities between the activated voxels in the estimated activation map.

“The statistical methods used in data analysis” very much depend on the type of available data. In neuroscience, the data are often (1) temporally correlated time series data and (2) multi-dimensional data, with dimension as large as 10–100 for EEG/MEG data and as large as 10,000 for fMRI data. Historically, statistical methods for neuroimaging data have been introduced using mostly those methods developed for identically distributed (i.i.d.) data. Direct application of conventional statistical methods to the analysis of high-dimensional temporally correlated neuroscience data often leads to difficulties

precisely because the data is very far from satisfying the i.i.d. assumptions. The “time series modeling approach” has been specifically designed to take temporal correlations and multi-dimensionality into account and so is much more appropriate for application to the analysis of neuroscience data than the conventional i.i.d. approach.

An important and critical point for the statistical analysis of neuroimaging data is not the algorithm we use for computing the activation map, nor is it whether the activation map looks attractive. The most important point is whether the “assumptions” employed for computing and producing the map are statistically valid and appropriate for the observed time series data.

One of the most widely used statistical methods for the analysis of fMRI data is the statistical parametric mapping (SPM) developed by Friston et al. (1995). In the first stage of SPM, the dynamic characteristic of the BOLD signal is identified using a deterministic dynamical system (the hemodynamic response function) embedded in the statistical framework of the general linear model (GLM). Here the model parameters are estimated under the assumption that the GLM errors are i.i.d. and normally distributed. An additional assumption is that the high-dimensional fMRI data is assumed to be spatially independent, meaning that no spatial dynamic interaction is allowed, considered, or tested between the voxels.

In the second stage of SPM, the estimated parameters for each voxel are used to check whether the voxel is activated or not using conventional hypothesis testing methods. The validity of the hypothesis testing approach depends critically on the assumptions behind the models used for evaluating the null and alternative hypotheses. The activated areas judged to be significant by the testing method are often plotted as an activation map on each slice of the scanned MRI figures. The guidelines for producing an activation map are somewhat arbitrary and depend on whether the researcher needs a simple picture of the functioning of the brain or something more complex. However, the use of the deterministic hemodynamic function,

the reliance on required assumptions such as normal i.i.d. errors, and the spatial independence are rather too strong and make SPM rather controversial. Unfortunately the checking of the validity of the assumptions is not provided in the paradigm of the hypothesis testing procedure, and it appears that many analysts may be ignoring this issue.

A less well-known but a rather more orthodox approach to the statistical characterization of the dynamics of the neuroimaging data such as fMRI and EEG/MEG time series data is the direct time series modeling approach (Riera et al. 2004; Galka et al. 2004; Friston et al. 2003). In this approach, the dynamic characteristics of the stimulus-activation relation in the brain function are directly specified by a time series model (or a dynamical system model) with exogenous inputs. A typical example is to use an autoregressive model with an exogenous variable (ARX model), where the activation effect dynamically caused by the exogenous input (i.e., a stimulus) is specified by the exogenous terms. Plotting the activation map is, again, quite arbitrary and depends on the scientists' objectives. Some researchers may plot the exogenous terms (which could sometimes be negative according to whether the vascular flow in the voxel increases or decreases) and some people may prefer to plot the significance of the exogenous terms (i.e., the difference of the log-likelihood of the full model (including exogenous variables) and the sub-model (excluding the exogenous variables)).

There are many other methods developed for the statistical analysis of neuroimaging data (see Poldrack et al. 2011; Ozaki 2012; Li 2014). Some methods employ dynamical system models where the models are assumed, a priori, to be deterministic (e.g., DCM (dynamic causal modeling) in Friston et al. (2003)). Most of the methods rely on the techniques developed in multivariate analysis such as GLM, PLS (partial least squares), SEM (structural equation model), ICA (independent component analysis), PCA (principal component analysis), etc. Here important dynamic information, contained in the data as temporal correlations, is neglected in the i.i.d. assumptions.

The validity of the results of statistical analysis and imaging depends critically on the model

identified from the data, where each model stands on its own assumptions (i.i.d., temporally correlated, deterministic, and stochastic Bayesian or non-Bayesian). In the statistical modeling approach, the most critical issue is how to find the best model using appropriate assumptions for the given data. In contrast to the hypothesis testing case, we can consider more than a hundred candidate models using different assumptions and lag orders. For the identification of the best model among these candidate models, several approaches are available in time series analysis. "The innovation approach" is known to be especially powerful and easy to use in situations where we need to choose the best model among many candidate dynamic models representing the same data. This is because it stands on a very simple principle, i.e., "Choose, among the finite set of candidate models, a model which can predict the future time series best." This principle is essentially equivalent to Akaike's information criterion (AIC) minimization principle which was introduced from the idea of maximizing the expected Boltzmann entropy. By including lagged variables and spatial variables into the model, the prediction error variance is substantially minimized and statistical validity may be achieved, since in the time series case, the temporal independence and the normality of the prediction errors are guaranteed for stationary continuous Markov processes (Doob 1953).

Higher-order correlation

Definition

Temporally precise correlations between simultaneously recorded neurons are interpreted as signatures of cell assemblies, that is, groups of neurons that coordinate their spiking activity to process information. Evidence of behavior-related pairwise correlations was found in simultaneous recordings of few neurons. Recent technological advances have enabled the recording of 100 or more neurons in parallel. Increasing the number of simultaneously recorded neurons enhances the chances to detect activities of both more and larger cell assemblies. Also, larger recordings enable to investigate more complex assembly-related activity patterns than synchronous spiking, such as spatio-temporal patterns (STPs) where neurons fire in sequence with specific temporal delays. However, these high-dimensional data raise considerable computational and statistical issues, thus requiring novel statistical tools for the analysis of correlations. SPADE, presented below, is one such a novel method, designed to reliably detect and statistically evaluate STPs for statistical significance in large scale spiking activity data.

Detailed Description

Introduction

Spatio-temporal spike patterns (STPs) are the most general form of temporally precise spike correlation. The definition includes spike synchrony (Grün et al. 2002a, b; see entry on ► “Joint Peri Stimulus Time Histogram (JPSTH)”); Shimazaki et al. 2012), delayed spike correlations and combinations of these, such as sequences of synchronous spike events (Schrader et al. 2008; Torre et al. 2016a). STPs are assumed as the signature of groups of neurons forming a cell assembly involved in information processing. STPs could be also part of larger and more complex forms of propagation of spiking activity, such as synfire chains (Abeles 1991) or synfire braids or polychrony (Bienenstock 1995; Izhikevich 2006, respectively).

The temporal coding hypothesis states that the brain relies on STPs of some sort to process

information at millisecond precision. This contrasts the rate coding hypothesis, which states – loosely speaking – that information is instead encoded in the neuronal firing rates at a slower temporal scale of several tens or even hundreds of milliseconds (Brette 2015; Riehle et al. 1997). Validating the temporal coding hypothesis thus requires to detect STPs in simultaneous neuronal recordings, to demonstrate that they occur beyond the chance level predicted based on the neuronal firing rates alone and to provide evidence that STP occurrence relates to cognitive tasks, such as different behaviors.

A variety of statistical methods have been developed to find statistically significant STPs in simultaneous recordings from few neurons (see, e.g., entry on ► “[Spatial Temporal Spike Pattern Analysis](#)”; Abeles and Gerstein 1988; Prut et al. 1998; Nádasdy et al. 1999). However, these methods do not trivially scale to simultaneous recordings from several tens or hundreds of neurons, where the number of possible patterns that need to be considered grows exponentially (up to billions). Counting the occurrences of each pattern raises a formidable computational issue, and testing for their statistical significance yields a considerable multiple testing problem. SPADE (Spike Pattern Detection and Evaluation) uses a data mining algorithm (frequent itemset mining, or FIM; Borgelt 2012) to count pattern occurrences in an effective way. Then, it uses a dedicated statistical procedure to assess, based on the pattern occurrence count, which patterns are statistically significant.

In Torre et al. (2016b), SPADE was applied to recordings from pre-/motor cortex of two monkeys trained to perform a delayed reach-to-grasp task. Specifically, animals were trained to perform a movement in one of four different options, which differed by the grip type used to grasp an object and the force required to pull the object. The authors focused on synchrony only and found statistically significant synchronous spike patterns with high specificity to the movement type. These patterns mostly involved two or three (and up to five) different neurons. Preliminary results on a broader analysis of nonsynchronous STPs

revealed repeating temporal sequences involving up to eight neurons, which are also highly specific to behavior. SPADE comprises three analysis steps, which are detailed below.

Retrieval of STPs

Identifying statistically significant patterns first requires to count the occurrences of each individual pattern. As the number of patterns grow exponentially with the number of recorded neurons, a linear search becomes infeasible when the number of simultaneously recorded neurons grows past a few units. For instance, $N = 100$ neurons can form up to $2^{100} \approx 10^{30}$ synchronous spike patterns and orders of magnitude more STPs of the general type. SPADE overcomes the hurdle with frequent itemset mining (FIM).

FIM originates from supermarket basket analysis, and searches shopping lists for items that customers frequently buy together. SPADE recasts the problem into that of detecting which neurons frequently spike synchronously (Torre et al. 2013; <https://www.youtube.com/watch?v=MRzwEKAWIYM>). The spike data are structured into a matrix where each column corresponds to a time bin (typically, a few milliseconds long) and each row contains the binary spiking activity (1 = active, 0 = silent) of each observed neuron. A synchronous pattern is defined as any set of active neurons inside the same time bin, and its occurrence count is given by the number of time bins where the pattern occurs. Of all observed patterns, only those occurring more than any of their supersets (closed) and occurring above a minimum number of times (frequent) are actually of interest. The FIM exploits the fact that supersets of infrequent patterns are themselves infrequent to considerably speed up this search.

For detection of spike patterns with temporal delays, that is, STPs, the spike data first need to be reformatted in such a way that STPs fall into the same column of the binary matrix. This is accomplished by sliding a window of w time bins along the original binary matrix in steps of one bin. At each step, the array of n neurons and w time bins covered by the matrix is reshaped into a column

vector of length $w \cdot n$. The column vectors are concatenated horizontally into a new binary matrix (Yegenoglu et al. 2016). FIM then analyzes this matrix to find closed frequent STPs (Quaglio et al. 2017).

STP Statistical Significance

To determine whether a closed frequent pattern is statistically significant, a straightforward approach also used in previous methods would be to compute the significance threshold of the occurrence count based on the neuronal firing rates under the rate coding assumption (e.g., Grün et al. 2002a, b; entry on ► “Unitary Event Analysis”). The pattern is classified as statistically significant if its occurrence count exceeds the significance threshold. A problem with this approach is that, in massively parallel spike train recordings, the large number of possible patterns would require excessively many statistical tests. False positives would be unavoidable, while on the other hand, correcting the significance threshold by the number of tests would yield a large number of false negatives.

SPADE circumvents this hurdle by first grouping patterns into classes based on three pattern features: the size z (number of neurons involved), the pattern occurrence count c , and the number of time bins between the first and the last spike of the pattern d . Instead of testing individual patterns, SPADE tests different pattern signatures $\{z, c, d\}$. A 4-dimensional matrix, called pattern spectrum, is built, containing for each signature the number of patterns with that signature found in the data. The significance of each signature is calculated by means of a Monte Carlo technique that generates surrogates of the original data (Louis et al. 2010; entry on ► “Surrogate Data for Evaluation of Spike Correlation”) under preservation of the firing rates while destroying potential millisecond-precise spike correlation (Stella et al. 2019).

Conditional Testing

Once a pattern signature is found as statistically significant, the patterns with the same signature may be nonchance events. Some of these patterns, however, may actually be the result of a chance

overlap of the actual patterns with background spiking activity. For instance, a cell assembly consisting of $z = 3$ neurons and producing $c = 7$ occurrences of a synchronous ($d = 0$) spike pattern may overlap with a fourth neuron which, by pure chance, happens to fire during 3 of the 7 activations of the assembly. This would produce a spurious synchronous pattern of size $z' = 4$ and an occurrence count $c' = 3$, which by the previous step would be wrongly classified as statistically significant, if the signature $\{4, 3, 0\}$ was also statistically significant. Many more combinations of such pattern overlap with background activity are possible and are very likely in recordings from many neurons. SPADE corrects for this misclassification by further testing the conditional significance of each pattern with a significant signature given any other pattern overlapping with it and also having a significant signature. Patterns resulting from chance overlap of actual patterns and background spiking activity are thereby removed (Torre et al. 2013).

Software

The SPADE analysis method is available as open source Python code (main function: `verbatim`) as part of the electrophysiology analysis toolbox Elephant (RRID:SCR_003833). The code can be found at: <http://python-elephant.org>. The implementation supports multithreading by MPI.

STEPS: STochastic Engine for Pathway Simulation

Iain Hepburn

Computational Neuroscience Unit, Okinawa
Institute of Science and Technology Graduate
University, Okinawa, Japan

Definition

STEPS is a molecular simulator with a focus on neuroscience applications, and so is designed to preserve and support important neuronal features such as complex morphology and electrical excitability. As such, STEPS simulates stochastic reaction-diffusion kinetics, 3D voltage calculations, ion channels, and membrane currents, all in tetrahedral mesh reconstructions of neuronal geometries. Since version 3.0, STEPS supports parallel solutions with proven scalability.

Detailed Description

Mesoscale Reaction-Diffusion Simulation in Tetrahedral Meshes

STEPS simulates stochastic molecular interactions, spatial concentration gradients, and diffusion. The category of reaction-diffusion simulators to which

STEPS belongs are often termed “mesoscale” where molecules are not tracked individually but instead space is discretized into small subvolumes in which populations of molecules are tracked. The subvolumes that STEPS supports are tetrahedrons, which allow representation of complex neuronal morphology to high accuracy (Hepburn et al. 2012), as demonstrated in Fig. 1.

The subvolumes display a characteristic size “window” in which the method is accurate, but errors become apparent with very small subvolumes in the nanometer range (Hepburn et al. 2012). As such, and in comparison to particle-tracking methods, the subvolume method has the advantage of allowing larger, more complex systems to be investigated due to better computational efficiency, although the smaller nanoscale of particle-tracking simulators cannot be reached.

STEPS supports multiple solvers including spatial, nonspatial, deterministic, and stochastic solutions, all of which share model construct within the Python interface. However, the main focus for STEPS development is on spatial stochastic simulation to enable simulations of high realism, particularly where key molecular players are sparsely, inhomogeneously populated, and so deterministic and well-mixed solutions are rendered inaccurate. Serial spatial stochastic simulations are based on Gillespie’s Stochastic Simulation Algorithm (SSA) (Gillespie 1977), extended for diffusion between tetrahedral

STEPS: STochastic Engine for Pathway Simulation,

STEPS: STochastic Engine for Pathway Simulation, Fig. 2 An example parallel STEPS spatial simulation in a fully reconstructed Purkinje cell dendrite, implementing the model of Anwar et al. 2013. The top panel displays

voltage and the bottom panel calcium over the shown ranges at five different time points through a dendritic calcium burst

elements by a finite volume method, an approach that is often termed “Spatial Gillespie” or “Spatial SSA.” The STEPS Spatial SSA method is continuously validated for accuracy with any code developments against a comprehensive set of reaction-diffusion models (Hepburn et al. 2012).

Voltage in 3D Neuronal Morphologies

STEPS implements a 3D voltage solution on tetrahedral meshes (Hepburn et al. 2013), with different options for the voltage calculations, including an original direct method that is suitable for smaller problems, and since version 3.1 a parallel, iterative solution based on the PETSc library (Balay et al. 1997) that is suitable for larger problems. The STEPS validation suite is extended for voltage calculations with the Rallpack benchmarks (Bhalla et al. 1992).

The 3D voltage solution on tetrahedral meshes allows STEPS to support membrane potentials, voltage-gated ion channels, and membrane currents in full 3D neuronal morphology. No 1D cable-like approximation is required, the full neuronal structure can be preserved if available (Chen and De Schutter 2017a). Tight integration with the reaction-diffusion computations allows investigation of the molecular and electrical components of neuronal signaling together, within realistic neuronal geometries. One example application is investigation of local, stochastic calcium

activation of ion channels in dendritic morphologies (Anwar et al. 2013).

Parallel STEPS on High-Performance Computers

Exact SSA methods are known to scale poorly, and so STEPS implements an operator-splitting approximation to the reaction-diffusion system in order to enable parallelism (Chen and De Schutter 2017b). In this approach, the spatial geometry is partitioned with Message Passing Interface (MPI) processes taking ownership of the resulting sets of tetrahedrons, one set per process. Stochastic reactions are then solved within the partitioned SSA in parallel. Diffusion is solved by a multinomial algorithm also in parallel, with cross-process diffusion events involving neighboring data transfer applied at predetermined time intervals. It has been shown that this operator-splitting approach demonstrates good accuracy in realistic biological models (Hepburn et al. 2016).

The MPI implementation of the operator-splitting reaction-diffusion system in STEPS has been shown to scale super-linearly in dendritic morphologies (Chen and De Schutter 2017b), and a known scalable library, PETSc (Balay et al. 1997), is implemented for voltage calculations in parallel STEPS enabling full parallel reaction-diffusion and voltage simulation with good scalability. Such simulations enable STEPS

to reach the whole cell scale with full stochastic reaction-diffusion kinetics of signaling molecules and ion channels, with an accurate, fast voltage solution in 3D neuronal morphologies (Fig. 2), allowing researchers to link biochemistry with electrophysiology to probe neuronal function in a computational setting.

Stereo Vision, Models of

Jenny Read
Institute of Neuroscience, Newcastle University,
Newcastle-upon-Tyne, UK

Synonyms

Models of 3D vision; Models of stereopsis

Definition

Due to the different location of the eyes in the head, objects at different distances from the observer project to slightly different locations in the two eyes. Stereo vision refers to the perception of depth based on these slight disparities between the images seen by the two eyes (Freeman 2009). This entry reviews models of stereo vision based on the real nervous systems. Stereo vision algorithms have also been developed independently within the machine vision literature, sometimes biologically inspired, but these are not within the scope of this entry.

Detailed Description

Stereo vision has two main steps: (1) extracting disparity from the retinal images and (2) perceiving depth structure from disparity. Although psychophysics experiments have probed both aspects, much more is known about the neuronal mechanisms supporting the extraction of disparity than about how and where in the brain disparity is converted into a perception of depth. This entry therefore concentrates on the first step. It seems that binocular disparity is initially encoded in the primary visual cortex (V1), which therefore acts as the “cyclopean retina” (Julesz 1971), that is, the first neural area which is able to detect features based purely on the differences between the two eyes images. There has been much work in recent years on how to model the response of disparity-selective neurons in V1 and how to decode this population activity in order to arrive at an estimate of the disparity at each point in the visual scene. In this entry, I aim to review this work.

Extracting Disparity from the Retinal Images

In primates, the first processing supporting specifically stereo vision is believed to occur in the primary visual cortex (V1). V1 is the first visual area to contain the neurons which receive inputs from both eyes and to be tuned to binocular disparity (Poggio et al. 1985). The most influential

model of disparity tuning in V1 is the stereo energy model, put forward by Izumi Ohzawa et al. (1990) and based in turn on similar models in the motion literature (Adelson and Bergen 1985).

Stereo Energy Model: Basic Unit

The basic idea behind the stereo energy model is a binocular neuron with a receptive field in each eye (Fig. 1). The input from each eye depends on the inner product of each eye's image with the corresponding receptive field. For example, the input from the left eye is

$$L = \int_{\text{retina}} dx dy I_L(x, y) \rho_L(x, y)$$

The function $I_L(x, y)$ represents the retinal image in the left retina, with luminance expressed relative to the mean, e.g., +1 = white, -1 = black, and 0 = gray. The function $\rho_L(x, y)$ represents the classical receptive field in the left retina, with 0 = no response (i.e., areas of the retina that are outside the receptive field), positive values corresponding to ON regions (areas where light stimulation tends to increase the cell's firing rate and dark suppresses it), and negative values to OFF regions (where dark features tend to increase the cell's firing and light suppresses it).

The energy model assumes that inputs from each eye are summed linearly. If the result is negative, the neuron is inhibited and does not fire. If positive, the neuron fires at a rate proportional to the square of the inputs:

$$S = [\text{Pos}(L + R)]^2 \quad (1)$$

where the notation $\text{Pos}(x)$ means half-wave rectification: $\text{Pos}(x) = x$ when $x > 0$, and $\text{Pos}(x) = 0$ otherwise. This model neuron is tuned to disparity both in monocularly visible features, e.g., the bar stimuli used in Ohzawa et al. (1990) and also in "cyclopean" stimuli such as dynamic random-dot patterns (Julesz 1971). Cyclopean stimuli contain features such as depth edges which are not visible monocularly but are revealed only by comparing the two eyes' images. A detailed analysis shows that the cyclopean disparity tuning is due to the output nonlinearity (Read 2005). A unit which simply summed left and right inputs linearly ($L + R$) would be tuned to the disparity of a bar stimulus, but only as a side-effect of its tuning to the position of monocular features. It would respond equally well, on average, to broadband noise images with any disparity. Thus, a nonlinearity is essential to produce cyclopean disparity tuning, i.e., to ensure that the cell responds more on average to broadband noise images with its preferred disparity. The threshold-and-squaring nonlinearity in Eq. 1 is used in many models of V1 neurons because it describes their

Stereo Vision, Models of, Fig. 1 Basic unit of the stereo energy model, after Ohzawa (1998). The graph on the right represents the squaring output nonlinearity. ON and OFF subregions of the receptive fields are shown in red and

blue, respectively. The receptive fields have the same orientation and spatial frequency but different phase. This cell would therefore be tuned to nonzero disparity

responses well. However, from a mathematical point of view, almost any nonlinearity would suffice to produce cyclopean disparity tuning.

The receptive fields are often represented by Gabor functions. Empirically, the spatial frequency and orientation tuning is similar between the eyes (Bridge and Cumming 2001; Read and Cumming 2003) and is usually modeled as being identical.

Position and Phase Disparity

The spatial location and phase (i.e., the location of ON and OFF subregions) of the two receptive fields may vary. These determine the preferred disparity of the unit. Position disparity shifts the disparity curve without altering its shape; phase disparity alters the shape. A phase disparity of 0 produces a curve which is symmetrical about a central peak, known as tuned excitatory. A phase disparity of π inverts this to give a curve with a central trough (tuned inhibitory). A phase disparity of $\pm\pi/2$ produces odd-symmetric curves with equally large peaks and troughs. Several models have been built using pure phase disparity (Sanger 1988; Fleet et al. 1991; Qian 1994; Qian and Mikaelian 2000). However, V1 contains cells with both position and phase disparity (Anzai et al. 1997; Prince et al. 2002). Several models therefore incorporate both position and phase (Chen and Qian 2004; Read and Cumming 2007).

Complex Cells

The unit in Eq. 1 is a simple cell, in that it is tuned to the phase of a grating stimulus (Movshon et al. 1978a). To build a complex cell, which is insensitive to grating phase (Hubel and Wiesel 1962; Movshon et al. 1978b), we can sum many such units with different receptive-field phases (Qian and Zhu 1997). A common computational shortcut is to sum just four such units, whose receptive fields differ in phase by multiples of $\pi/2$ (Fig. 2). This produces a complex cell whose response is perfectly independent of grating phase. Note that this difference in phase must not be confused with

the phase disparity discussed above. Phase disparity refers to a difference between the left- and right-eye receptive fields of a given energy-model unit ($\phi_R - \phi_L$ for each unit in Fig. 2). Here, we are talking about a difference in phase between receptive fields of different units, in the same eye (the four different ϕ_L in Fig. 2).

Modifications of the Energy Model

Several modifications have been proposed to the original energy model outlined above. One problem with the original energy model is that it responds equally strongly to disparity in anti-correlated random-dot patterns. These are non-physical stimuli in which one eye's image is the photographic negative of the other (Fig. 3). This manipulation all but destroys depth perception (Cogan et al. 1993; Cumming et al. 1998; Read and Eagle 2000). Since this corresponds to changing the sign of I_R relative to I_L , it simply inverts the disparity tuning of an energy-model unit (Eq. 1). However, the response of real V1 neurons is attenuated as well as inverted (Cumming and Parker 1997). To capture the attenuation, Read et al. (2002) proposed thresholding the inner products L and R before summing them in Eq. 1. A similar approach was also proposed by Tanaka and Ohzawa (2006) to explain second-order stereopsis. Lippert and Wagner (2001) proposed changing the squaring nonlinearity. Adding an expansive nonlinearity to tuned-excitatory cells, or a compressive nonlinearity to tuned-inhibitory cells, can produce the desired effect. Haefner and Cumming (2008) showed that a similar approach captures the response of V1 cells to a wide range of nonphysical stimuli. Samonds et al. (2013) incorporated recurrent connections within V1 to account for the temporal dynamics of disparity tuning, as well as the attenuated response to anti-correlated images.

All these versions of the energy model predict a strong relationship between a cell's preferred orientation with grating stimuli and its tuning to 2D disparity. Binocular disparity is in principle 2D since the two eyes' images can be offset both horizontally and vertically, although

Stereo Vision, Models of, Fig. 2 Stereo energy-model complex cell, after Ohzawa (1998). The complex cell C represents the summed output of 4 of the basic units shown in Fig. 1, with different phases ϕ as labeled. The *top* two units have receptive fields which are the opposites of one another (π out of phase). This has the effect of removing the threshold before the squaring. To see why, let us call the output of the *top* S cell $[\text{Pos}(L_1 + R_1)]^2$. This is $(L_1 + R_1)^2$ when $(L_1 + R_1) > 0$, and 0 otherwise. Since the

second S cell has the same RFs, only inverted, its output will be $[\text{Pos}(-L_1 - R_1)]^2$. This is $(L_1 + R_1)^2$ when $(L_1 + R_1) \leq 0$, and 0 otherwise. Together, the sum of the two S cells is therefore $(L_1 + R_1)^2$. The *bottom* pair of cells is $\pi/2$ out of phase with the *top* pair, an arrangement known as *in quadrature*. This makes the response of the complex cell independent of the phase of the stimulus, essentially due to the trigonometric identity $\cos^2 + \sin^2 = 1$

Stereo Vision, Models of,

Fig. 3 Anticorrelated random-dot stereogram. Note that *black* dots in the left eye are *white* in the right, and vice versa

in normal viewing the horizontal component is much larger (Read et al. 2009). The energy model predicts that cells should be more

sensitive to disparities perpendicular to their preferred orientation than to those parallel to it. This prediction is borne out in the peripheral

visual field in monkey (Durand et al. 2007) and in cat (Sasaki et al. 2010) and represents another success for the energy model. Matthews et al. (2003) exploited this property of the energy model, along with the radial bias of preferred orientations in the visual cortex, in order to develop a model of depth perception from vertical disparity. However, in the central visual field, Cumming (2002) reported that V1 neurons tend to be more sensitive to vertical than to horizontal disparity, irrespective of their orientation. One way to modify the energy model to account for this property is to include multiple subunits scattered more widely horizontally than vertically (Read and Cumming 2004).

The Energy Model and Time

The original energy model included no dependence on time. A more realistic model would include receptive fields whose response depends on time as well as on spatial location. This is important for capturing effects such as our poor temporal resolution for disparity (Norcia and Tyler 1984) or the Pulfrich illusion (Morgan 1976). Qian and Andersen (1997) were the first to modify the energy model to include time. Their model is tuned to both direction and disparity, which is relatively unusual experimentally: many V1 neurons are tuned to disparity but not direction (Read and Cumming 2005). Additionally, in many V1 neurons, interocular delay simply reduces the amplitude of disparity tuning without shifting the preferred disparity (Read and Cumming 2005). It is difficult to reconcile this with the temporally band-pass tuning that V1 neurons typically show to luminance, i.e., they respond better to flickering than to constant stimuli. If one simply adds temporally band-pass receptive fields to the energy model, the model predicts that disparity tuning will invert for certain interocular delays. This is rarely observed (Read and Cumming 2005). Accordingly, work remains to be done on producing a model which captures the disparity response of real V1 neurons in the time domain.

Solving the Correspondence Problem

V1 cells are local, seeing only a small region of each retina. They respond to “false matches,” image features which look similar but are caused by different objects in space, as well as to corresponding views of the same object. To disambiguate these, it is necessary to solve the “correspondence problem,” correctly matching up image features in both eyes’ images (Ohzawa 1998). This process is not completed in V1. Anticorrelated stereograms are one piece of evidence for this. As noted, V1 cells continue to respond to these non-physical stimuli, albeit with attenuation, whereas cortical areas further down the processing pathway, for example, IT, do not (Janssen et al. 2003).

Models of stereo correspondence predate detailed knowledge of disparity encoding in V1 (Marr and Poggio 1979; Pollard et al. 1985). More recently, modelers have sought to understand how the correspondence problem could be solved by appropriately combining populations of V1-like neurons (Qian 1994, 1997).

One approach is to consider a population of cells which differ only in their tuning to disparity and take the stimulus disparity to be the preferred disparity of the maximally responding V1 cell (Qian 1994). However, often this will not be the correct answer, for two main reasons. First, the energy model is not sensitive to the precise arrangement of luminance within the receptive field; this information is lost when the inner product is computed (Eq. 1), and its response depends on image contrast. Therefore, an energy-model unit will respond well to a false match which happens to stimulate the left and right receptive fields strongly, even if the image within each receptive field is quite different. To overcome these problems, it helps first to normalize out the cell’s response to contrast (Sanger 1988; Read and Cumming 2006; Read 2010), e.g.:

$$C = \frac{2LR}{L^2 + R^2} \quad (2)$$

Such divisive normalization has been found in many brain areas and is so widespread that it has been proposed as a canonical computation of the

cortex (Carandini and Heeger 2012). In the present case, the division transforms unnormalized energy, similar to a cross-correlation function (Qian and Zhu 1997), to a normalized correlation, bounded between -1 and $+1$. Now, the preferred disparity of the maximally responding C unit is guaranteed to be the correct stimulus disparity, if the stimulus disparity is exactly constant over the cells' receptive fields (Read and Cumming 2007). However, for more realistic situations, where disparity varies across the image, this approach too can fail.

Greater robustness is obtained by expanding the population under consideration to include cells tuned to a range of orientations and spatial frequencies/spatial scales as well as to a range of disparities. Fleet and colleagues (Fleet 1994; Fleet et al. 1996) proposed a linear pooling of neuronal responses across orientations and scales. Allenmark and Read (2011) showed that by pooling across orientations and spatial frequencies and then normalizing as in Eq. 2, one effectively computes the cross-correlation of the left and right retinal image patches. This linked the physiologically based stereo energy model to a class of more abstract models based on windowed cross-correlation of the retinal images, which had successfully captured several aspects of human vision (Tyler 1974, 1975, 1978; Banks et al. 2004; Nienborg et al. 2004, 2005; Filippini and Banks 2009).

Tsai and Victor (2003) used a template-matching approach pioneered in this area by Lehky and Sejnowski (1990). Their population includes neurons tuned to a range of spatial frequency and phase disparities. They compute the mean response of this population to "template" noise stimuli with uniform disparity. The disparity in any given stimulus is taken to be that of the template which best matches the population response. Their model also allows for the perception of *transparency* (multiple planes at different depths) when multiple templates match similarly well, capturing several aspects of human perception (McKee and Verghese 2002). Other aspects of transparency appear to require excitatory and inhibitory interactions between disparity-tuned neurons (Tsirlin et al. 2012).

Monocular Occlusions

A feature of binocular vision first studied by Leonardo da Vinci is that some image features may be visible to only one eye. These monocular occlusions present a special challenge for establishing correspondence. A few biologically inspired models suggest how these regions may be handled in the brain (Watanabe and Fukushima 1999; Hayashi et al. 2004; Assee and Qian 2007).

Perceiving Depth Structure from Disparity

Once the stereo correspondence problem has been solved, we have a "disparity map" specifying image disparity at every point in the visual field. This must then be converted into a perception of depth. Relative depth (i.e., "object A is in front of object B") can be deduced immediately from the relative disparity between them. Humans are much more sensitive to the relative disparity between objects or surfaces than to the absolute disparity of an isolated object (Westheimer 1979; Parker 2007).

Further evidence that neurons in the primary visual cortex (V1) do not directly support depth perception is provided by the fact that their response is determined by the absolute disparity of the stimulus within their receptive field, not by the disparity relative to other objects in the scene (Cumming and Parker 2000). The extraction of relative disparity appears to begin in the cortical area V2, where neurons that are found are sensitive to relative disparity and are specifically tuned for disparity edges (von der Heydt et al. 2000; Thomas et al. 2002; Bredfeldt and Cumming 2006). These neurons' responses can be modeled by combining the output of different energy-model units (Bredfeldt et al. 2009).

For metric depth (i.e., "object A is 10 cm in front of object B"), disparity must be calibrated by a knowledge of the eye position. In theory, this can be obtained from extra-retinal signals (proprioception, efference copy) or from purely retinal signals if 2D disparity is available. As noted above, disparity in natural viewing is

overwhelmingly horizontal, but vertical disparities also occur, in a pattern which is dependent on the eye position and largely independent of the scene viewed. In theory, therefore, the eye position can be recovered from the 2D disparity map (Longuet-Higgins 1982). There is psychophysical evidence that vertical disparity is indeed detected by the human visual system and used to guide perception (Rogers and Bradshaw 1993, 1995; Garding et al. 1995; Backus et al. 1999). However, little is known about the underlying neuronal mechanisms or the cortical areas involved. Detailed neuronally based models have therefore not been constructed.

Stimulus Reconstruction from Cortical Responses

Nima Mesgarani
Department of Electrical Engineering, The Fu Foundation School of Engineering and Applied Science, Columbia University, New York, NY, USA

Definition

Reconstruction is a technique used to recreate a stimulus from its corresponding neural responses. By projecting the cortical representation of stimulus in the neural space back to the physical domain where it is usually better understood, reconstruction provides a straightforward and direct method to study the stimulus features encoded by the population neural data. Reconstruction has also been used to decode the perceived or imagined stimuli from the measurements of brain activity.

Detailed Description

Background

Cortical neurons encode considerable details about stimuli which could be difficult to discern because of the complexity and diversity of cortical receptive fields. The typical approaches used to understand the cortical representation of stimuli include examining the distribution of tuning properties for a population of neurons (De Valois et al. 1982; Ferragamo et al. 1998; Woolley et al. 2005) and pre-stimulus time histogram sorted with respect to selectivity to various stimulus parameters (Sachs et al. 1983; Mesgarani et al. 2008). Although useful, these methods are limited in their scope, especially when not all the relevant parameters of the neural space are understood and when dealing with complex stimuli that vary along numerous, possibly correlated dimensions. Stimulus reconstruction is an alternative for studying what aspects of the stimuli are encoded in the cortical responses and provide a direct comparison with the original signal.

Methods

Estimating the stimulus from responses can be done in various ways, including linear or non-linear transformations applied to the population of neural data (Bialek et al. 1991; Rieke et al. 1995; Warland et al. 1997; Haag and Borst 1998; Stanley et al. 1999; Shpigelman et al. 2005; Mesgarani et al. 2009) or formulating this problem in a statistical inference framework (Pillow et al. 2005; Paninski et al. 2007).

Stimulus Statistics

It has been shown that imposing known stimulus structures and its prior distribution can

significantly improve the accuracy of reconstruction (Mesgarani et al. 2009; Pillow et al. 2011; Ramirez et al. 2011). This is particularly useful if the reconstruction is used to approximate the best possible stimulus from cortical activity. However, if the reconstruction is used to examine stimulus features that are explicitly encoded in the neural data, inclusion of stimulus correlations may result in misleading conclusions. For example, if a correlated feature is not explicitly encoded in the neural data, it can still be reconstructed from its co-occurrence with another aspect of stimulus that is encoded [see Fig. 3 in (Mesgarani et al. 2009) for a simulation explaining this idea].

Applications

Stimulus reconstruction has been used in a variety of contexts, from decoding perceived or imagined information in the brain (Thirion et al. 2006; Naselaris et al. 2011; Pasley et al. 2012) to studying how the dynamic internal state of an organism changes the population encoding of stimulus in the cortex (Ding and Simon 2012; Mesgarani and Chang 2012).

Stimulus-Specific Adaptation, Models

Robert Mill

MRC Institute of Hearing Research, Nottingham, UK

Definition

Stimulus-specific adaptation (SSA) refers to a reduction in neural activity due to the repeated presentation of a stimulus, which does not generalize to other stimuli (Ulanovsky et al. 2003). SSA is present in auditory cortex (Ulanovsky et al. 2003), thalamus (Antunes et al. 2010), and inferior colliculus (IC) (Malmierca et al. 2009), but not the cochlear nucleus (Ayala et al. 2013). SSA has attracted interest on account of its similarity to mismatch negativity (MMN) in human auditory evoked potentials (Nelken and Ulanovsky 2007; cf. Farley et al. 2010). Computer models of SSA aim to capture the main features of single and multiunit responses to sequences of stimuli containing rare, or novel, events.

Detailed Description

Measuring SSA

Several methods exist for measuring SSA. In the simplest case, one can measure the effect of one or more *conditioner tones* on the neural response to a *probe tone* with respect to some feature, e.g., frequency (Fig. 1a). Other studies measure the average adaptation to long patterns of tones (Fig. 1b). In this case, each tone in the sequence effectively serves as both a conditioner and a probe.

SSA is most commonly investigated using *oddball sequences*, in which a rare tone (*deviant*) is presented in the context of a common tone (*standard*) (Fig. 1c). Oddball sequences are typically presented twice, with the deviant and standard features exchanged on the second

presentation. A *specificity index* (SI) provides a normalized measure of the degree of SSA:

$$SI = \frac{d_A - s_A + d_B - s_B}{d_A + s_A + d_B + s_B}$$

Here, s_X and d_X measure the activity evoked by tone X in the standard and deviant context, respectively. SSA is indicated when the SI significantly exceeds zero. Oddball sequences typically comprise several hundred tones.

Principal Results from SSA Studies

Most SSA studies use oddball sequences containing two frequencies and vary the frequency difference (Δf), the time difference between consecutive tones (Δt), and the probability of the deviant tone (p_{dev}). SI increases monotonically as:

- Δf increases
- Δt decreases
- p_{dev} decreases

How SSA elicited by other deviant features, such as intensity, duration, and amplitude modulation, should be interpreted remains a matter of contention.

Local History Models

Local history models of SSA attempt to account for the response to a tone solely in terms of the tones preceding it (Ulanovsky et al. 2004). For instance, if a tone A presented in the context ...ABAAX, then SSA neurons fire more vigorously when $X = B$ than when $X = A$. An explicit local history model stores recent tones in a finite memory of length L and responds only when this memory indicates that the incoming tone is deviant (Mill et al. 2011a). This type of model is illustrated in Fig. 2a for $L = 3$. Provided that A and B are confusable on the basis of their similarity, the model can account for the Δf and p_{dev} relations described above. However, the

Stimulus-Specific Adaptation, Models,

Fig. 1 Experiments used to explore SSA. (a) Cartoon showing how a conditioner tone (purple) affects the response to a probe tone (yellow and green). The adaptation of the probe may depend only on the response to the conditioner (no SSA, top right) or a combination of the probe and conditioner frequencies (SSA, bottom right) (Brosch and Schreiner 1997; Scholes et al. 2011). (b) Stimuli configurations used in other SSA experiments. The average response to a tone in the block, sequential,

random configurations is smallest for the block stimulus and largest for the random stimulus (Pérez-González et al. 2005). In the roving oddball paradigm, the first and last tones are treated as standards and deviants, respectively (Bäuerle et al. 2011). (c) Schematic responses (above) to oddball stimuli (below). In the first presentation (left), tone B is the oddball. In the second presentation (right), tone A is the oddball. For these example sequences and measurements, SI $\approx$ 0.29

observation that more recent tones exert a stronger suppressive influence on the incoming tone lends greater support to a *decaying memory* model.

Decaying memory models assign to each stimulus X a resource, R_X , possibly corresponding to synaptic neurotransmitter (Taaseh et al. 2011). The activity elicited by X is then proportional to R_X . The resource decays following presentations of stimuli similar to X and undergoes a steady recovery in the meantime. A basic example is a model which, when presented with tone X , first responds with R_X and then updates for R_Y , $Y = \{A, B\}$, according to

$$\begin{aligned} R_Y &\leftarrow \alpha R_Y & \text{if } Y = X \\ R_Y &\leftarrow R_Y + \beta(1 - R_Y) & \text{if } Y \neq X \end{aligned}$$

Figure 2b shows the output of this model using $\alpha = 0.5$, $\beta = 0.1$ for a short example oddball

sequence. A model this simple can account for the p_{dev} relation.

In order to also explain the Δf relation, it must be modified so that similar stimuli either consume overlapping resources (Mill et al. 2011b, 2012; Taaseh et al. 2011) or are liable to be confused with each other (Mill et al. 2011a). Figure 2c shows an example output from the model described in Mill et al. (2012), in which resources, $R(x)$, are distributed along a continuous feature axis, x , and are consumed and recovered in continuous time. Inputs are modeled as pulses, separated by Δt in time and Δf in feature space.

Global History Models

Besides the short-term effects captured by a decaying memory model (~ 1 s), neurons exhibit

Stimulus-Specific Adaptation, Models, Fig. 2 Output from simple SSA models. (a) In a two-tone oddball condition, a deviant response is generated to an incoming tone if it represents less than half of the items in a trailing memory of length $L = 3$. The computation of the deviant response to the last tone is highlighted in the figure (see Mill et al. 2011a). (b) Response exemplifying a decaying

memory model (see text). The top row shows the response; the middle rows show the resource state; the bottom row shows the stimulus pattern. (c) Response from the model described by Mill et al. (2012) ($SI \approx 0.04$). Inputs and resources are described in spatially continuous, rather than categorical, terms

additional decay components in their response to both standards and deviants that span longer time scales (~ 10 – 100 s) (Ulanovsky et al. 2004; Zhao et al. 2011; Bäuerle et al. 2011; Pérez-González et al. 2012). Whereas the depression of the thalamocortical synapses provide a plausible mechanism for the rapid time course (e.g., Ulanovsky et al. 2004), the biophysical mechanisms responsible for the slower time courses remain obscure.

Global dependence on the deviant probability, p_{dev} , is captured by a phenomenological regression model (Ulanovsky et al. 2004; Zhao et al. 2011), which fits the response to the n th tone according to the linear combination:

$$y_n = c_0 + c_1 M_n + c_2 p_{\text{dev}}$$

Here the coefficients c_0 , c_1 , and c_2 are free parameters, and M_n is a recent memory term computed using

$$M_n = \left(\frac{1}{Y} - 1 \right) \sum_{i=1}^{\infty} \gamma^i S_{n-i}$$

where γ is a decay parameter and $S_i = 1$ if the $(n - i)$ th tone identical to the n th tone and $S_i = 0$ otherwise.

Information Transmission

Ulanovsky et al. (2004) showed that auditory cortical responses to tones in an oddball sequence are proportional to their *unexpectedness*, defined in terms of the regression model described above. Mill et al. (2011a) reinforced this conclusion by demonstrating that a decaying memory model with rapid adaptation and slow recovery, when presented with a sequence containing multiple stimuli (e.g., $X \in \{X_1, X_2, \dots\}$), responds approximately in proportion to the stimulus entropy, i.e., $E\{-\ln P(X_i)\}$, provided that the stimuli adapt

Stimulus-Specific Adaptation, Models,
Fig. 3 Decaying memory model response versus entropy. Mean response of the decaying memory model ($\alpha = 0.5$, $\beta = 0.1$; see “Local History Models”) to

sequences containing 2 (oddball), 3, or 4 stimuli plotted against the entropy of the sequence. Note that the entropy of an oddball sequence in bits is $-p_{\text{dev}} \log_2 p_{\text{dev}} - (1 - p_{\text{dev}}) \log_2 (1 - p_{\text{dev}})$ (Adapted from Mill et al. (2011a))

distinct channels (Fig. 3). SSA may thus constitute a mechanism to reduce redundancy in the neural signal as it ascends the auditory pathway (cf. Chechik et al. 2006).

Rarity Versus Novelty

SSA can be interpreted within the oddball paradigm as *novelty detection*: deviant stimuli are conspicuous against the background of a common standard. This prompts a concern that SSA may reflect only rarity and not novelty per se (Fig. 4a). In response, researchers have devised a control condition, in which the deviant tone is presented among many standards, such that it is equally rare but otherwise unremarkable (see Fig. 4b) (Jacobsen and Schröger 2001; Farley et al. 2010; Taaseh et al. 2011).

Single-cell recordings in auditory cortex have revealed both enhanced responses to stimuli presented in the single-standard context (Ulanovsky et al. 2003) and near-equal responses (Farley

et al. 2010; Taaseh et al. 2011). This inconsistency has been attributed to differences in cross-adaptation resulting from the spacing of control standards. Moreover, an equal response in the two conditions fails to demonstrate insensitivity to novelty conclusively. Taaseh et al. (2011) show that a decaying memory model actually predicts appreciably smaller responses to deviants in the single-standard condition than in the many-standards condition. Consequently, an excess in the response to novel stimuli remains to be explained.

Mill et al. (2011b) have proposed a model containing two layers of adaptation in series that enhances responses to genuinely novel stimuli. The model is illustrated in Fig. 4c, d. In this model, adaptation to individual frequencies occurs at the first layer. The outputs from this layer are then subject to further adaptation at the second layer. When many standards are presented, the (representative) unit in the first layer is highly responsive (see “Information Transmission” above) and the unit in the second layer is adapted

Stimulus-Specific Adaptation, Models,
Fig. 4 Control conditions and models of the novelty response. (a) Diagram contrasting rarity versus novelty. The red stimulus appears 20% of the time but is only novel in the *top row*. (b) Illustration of the single-standard condition (*left*) and multiple-standard control condition (*right*). (c) Response of a two-layer model to multiple standards (*left*) followed by a deviant (*right*), which generates little or no novelty response. (d) Response of a two-layer model to a single standard (*left*) followed by a deviant (*right*), which generates a stronger novelty response (Mill et al. 2011b, Adapted from Fig. 2c, d)

(Fig. 4c). Conversely, when a single standard is presented, the unit in the first layer undergoes adaptation, and the unit in the second layer recovers (Fig. 4d). Novelty responses are coded in the second layer.

Modulation of SSA by Inhibition

A convergence of depressing synapses conveying specific-stimulus signals suffices to explain many aspects of SSA (see above). However, recent studies have highlighted the contribution of inhibition in shaping the adaptation. Blocking inhibitory (GABA_A) receptors increases the responsiveness of IC neurons to both standards and deviants, but alters the overall response ratio such that the SI is smaller (Pérez-González et al. 2012). Furthermore, examining the difference between the

poststimulus time histograms for deviant and standard tones reveals a subpopulation of cells that respond more vigorously to the standard than to the deviant after the stimulus onset. This tendency becomes more widespread following the application of the inhibitory blocker gabazine (Pérez-González and Malmierca 2012). Inhibition has to date assumed a marginal role in SSA modeling (e.g., Mill et al. 2011b); it is clear, however, that inhibition strongly modulates SSA, and future detailed models must account for it.

Stimulus-Specific Information

Michael Wehr

Institute of Neuroscience, University of Oregon,
Eugene, OR, USA

Definition

Stimulus-specific information is an information-theoretic measure of how much information the responses of a neuron convey about a particular stimulus. It is closely related to specific information, which is a measure of the information that a given neuronal response provides about which stimuli were presented. The stimulus-specific information is the average of the specific information across all the responses that occur when a particular stimulus is presented.

Detailed Description

Stimulus-specific information (SSI) (Butts 2003; Butts and Goldman 2006) is typically computed for sensory neurons that selectively respond to sensory stimuli, such that their selectivity can be characterized by a tuning curve or receptive field. For example, auditory neurons are typically tuned to sound frequency. SSI is given by

$$SSI(.,f) = \sum_r p(r|f) i_{sp}(r)$$

where f is sound frequency (or, equivalently, any stimulus dimension, such as orientation), r is the neuronal response, and i_{sp} is the specific information (DeWeese and Meister 1999), which is given by

$$i_{sp} = -\sum_f p(,f) \log_2 p(,f) \\ + \sum_f p(f|r) \log_2 p(f|r)$$

Note that $p(f)\log_2 p(f)$ is the entropy $H(f)$, so the specific information can also be written as

$$i_{sp} = H(,f) - H(f|r)$$

Here, $H(f)$ is the entropy of the stimulus ensemble, which can also be thought of as the number of possible stimuli and therefore also as the amount of uncertainty about the stimulus. $H(f|r)$ is this uncertainty given that a particular response r occurred. Thus, $i_{sp}(r)$ measures the reduction in uncertainty about the stimulus that is provided by response r or, in other words, the amount of information provided by the response r . Note that the choice for how to quantify the neuronal response r is not specified. For example, it could be firing rate, spike latency, or any arbitrary temporal code.

$SSI(f)$ is the i_{sp} averaged over all the responses r that occur when stimulus f is presented. It therefore represents how much information a neuron provides, on average, about that stimulus.

An important detail to remember when computing SSI is that information measures are subject to bias. This bias comes from the limited number of trials in experiments, which causes undersampling of the probability distributions in the above equations (for review, see Panzeri et al. 2007). There are several methods that attempt to correct for this bias. Probably, the simplest one is to compute SSI as above, but with all stimulus-response combinations randomly shuffled. In this case, the true SSI is zero, but the calculation will produce some positive value, which is caused by the bias. This value can be averaged and used as an estimate of the bias and subtracted from the raw SSI calculated above:

$$SSI_{\text{corrected}} = SSI - \langle SSI_{\text{shuffled}} \rangle$$

Note that some response types (such as temporal codes) have many more possible values than

others (such as firing rates). The probability distributions for such codes therefore require correspondingly more data to sample and, for a given data set, would therefore be more susceptible to bias.

SSI can also be computed for a population of neurons, in a similar fashion to that for individual neurons. In this case, the response r is replaced by a vector of responses $\vec{r} = [r_1, r_2, \dots, r_N]$ for the population of N neurons (Butts and Goldman 2006). Again note the expected combinatorial increase in data requirements for sampling the response probability distributions.

Variability and Information

High SSI for a stimulus means that the stimulus is well encoded. This happens when uncertainty about the stimulus is reduced by the response. This hinges on the reliability of the response, and SSI is therefore strongly influenced by variability in neuronal responses. Variability in the response to a given stimulus (many different r s evoked by a single f) will reduce the amount of SSI.

The effect of variability on SSI leads to an intriguing tuning curve phenomenon that has important implications for neural coding (Butts and Goldman 2006). Sensory neurons are often thought of as feature detectors, whose responses signal how close a stimulus is to the preferred stimulus of the neuron. In this view, one would expect maximal SSI for the preferred stimulus, at the peak of the tuning curve. However, the flanks of the tuning curve, which have the steepest slope, also convey information about the stimulus. In the steep flanks, small changes in the stimulus produce large changes in the firing rate. Because the slope of the tuning curve is flat near its peak, responses to neighboring stimuli will be similar, and neurons may therefore be less able to discriminate stimuli near their best stimulus, compared to those in the flanks. In this view, one would expect maximal SSI in the flanks of the tuning curve, not the peak. Thus, these two intuitive views of neuronal tuning make quite different predictions

Stimulus-Specific Information, Fig. 1 The effect of variability on SSI. (a), *Top*, Tuning curve of a model neuron with a high level of additive Gaussian noise (generating high response variability). *Dotted lines* indicate one SD. *Bottom*, SSI across stimuli. Maximal SSI was aligned with peak of the tuning curve (vertical dashed line). (b),

Same tuning curve but with low noise (and low response variability). Maximal SSI has now shifted to the points of steepest slope in the tuning curve (vertical dashed lines). (c), SSI curves across a range of variability levels, showing the transition of maximal SSI from peak to slope of the tuning curve

about the most informative region of the receptive field. The dependence of SSI on response variability reconciles these different predictions, so that both interpretations can be correct depending on neuronal variability (Butts and Goldman 2006). When trial-to-trial variability is high, a model neuron conveys maximal stimulus-specific information at the peak of its tuning curve (Fig. 1a). As trial-to-trial variability is reduced, the maximal information gradually shifts to the steep flanks of the tuning curve (Fig. 1b, c). This unified framework suggests that neural coding strategies depend critically on the level of neuronal variability. A recent study of neurons encoding sound frequency in auditory cortex demonstrated that maximal SSI was always at

the best frequency and never in the tuning curve flanks (Montgomery and Wehr 2010). This suggests that despite the high reliability of auditory cortical neurons, they are too variable to be most informative at the flanks of their tuning curves and instead act as feature detectors for their best frequency.

Stochastic Neural Field Theory

Paul Bressloff

Department of Mathematics, University of Utah,
Salt Lake City, UT, USA

Definition

One of the major challenges in neuroscience is to determine how noise that is present at the molecular and cellular levels affects dynamics and information processing at the macroscopic level of synaptically coupled neuronal populations. Often noise is incorporated into deterministic neural network models using extrinsic noise sources. An alternative approach is to assume that noise arises intrinsically as a collective population effect, which has led to a master equation formulation of stochastic neural networks. Stochastic neural fields are obtained by taking a continuum limit of a stochastic neural network with spatially structured synaptic weights.

Detailed Description

The spike trains of individual cortical neurons *in vivo* tend to be very noisy, having interspike interval (ISI) distributions that are close to Poisson (Softky and Koch 1993). The main source of intrinsic fluctuations at the single-cell level is channel noise, which arises from the variability in the opening and closing of a finite number of ion channels (Faisal et al. 2008). On the other hand, extrinsic fluctuations in membrane voltage are predominantly due to synaptic noise. That is, cortical neurons are bombarded by thousands of synaptic inputs, many of which are not correlated with a meaningful input and can thus be treated as background synaptic noise (Brunel 2000). It is not straightforward to determine how noise at the single-cell level translates into noise at the population or network level. Neural field equations can be derived under two basic assumptions: (i) the spike trains of individual neurons are decorrelated (asynchronous) so that the total synaptic input to a neuron is slowly varying and deterministic and (ii) there exists a well-defined continuum limit of the resulting network rate equations. So far there has been no rigorous proof that either of these assumptions hold in large-scale spiking network models of cortex. In particular, there has been no systematic scaling up of spiking networks to derive continuum neural field models that take proper account of noise-induced fluctuations and statistical correlations between neurons at multiple spatial and temporal scales. Consequently, current formulations of stochastic neural field theory tend to be phenomenologically based. One approach is to consider a Langevin version of deterministic neural field equations involving some form of extrinsic spatiotemporal noise (Hutt et al. 2008; Faugeras et al. 2009; Bressloff 2012; Bressloff and Webber 2012a), whereas another is to treat the neural field equations as the thermodynamic limit of an underlying master equation (Buice and Cowan 2007; Bressloff 2009; Buice et al. 2010). In the latter case, a diffusion approximation leads to an effective Langevin equation with multiplicative noise. In order to develop the theory of stochastic neural fields, it is useful to consider discrete network models first (Bressloff 2012).

Langevin Equation Formulation

Consider a set of P homogeneous populations labeled $i = 1, \dots, P$. Suppose that population activity is given by a stochastic variable $A_j(t)$ evolving according to a Langevin equation (stochastic differential equation) of the form

$$\hat{\tau} dA_j(t) = [-A_j(t) + F(U_j(t))]dt + \sigma_j dW_j(t), \quad (1)$$

where F is a population rate function and $U_j(t)$ is a stochastic synaptic current satisfying the integral equation

$$U_j(t) = \sum_{k=1}^P \int_{-\infty}^t \Phi_{jk}(t-t') A_k(t') dt'. \quad (2)$$

Here $\Phi_{jk}(t)$ represents the temporal filtering effects of synaptic and dendritic processing of inputs from any neuron of population k to any neuron of population j . In Eq. 1, $W_j(t)$, $j = 1, \dots, P$, denotes a set of P -independent Wiener processes with

$$\langle dW_j(t) \rangle = 0, \langle dW_j(t) dW_k(t) \rangle = C_{ij} dt. \quad (3)$$

Here C_{ij} incorporates any spatial correlations and σ_j is the strength of noise in the j th population. In general, the resulting stochastic model is non-Markovian. However, if we take $\Phi_{jk}(t) = w_{jk} \Phi(t)$ with $\Phi(t) = \tau^{-1} e^{-t/\tau}$ (exponential synapses), then we can convert the latter equation to the form

$$\tau dU_j(t) = \left[-U_j(t) + \sum_{k=1}^P w_{jk} A_k(t) \right] dt \quad (4)$$

It is important to note that the time constant $\hat{\tau}$ cannot be identified directly with membrane or synaptic time constants. Instead, it determines the relaxation rate of a local population to the mean-field firing rate. In the limit $\hat{\tau} \rightarrow 0$, Eqs. 1 and 4 reduce to a *voltage-based* rate model perturbed by additive noise:

$$\tau dU_j(t) = \left[-U_j(t) + \sum_{k=1}^P w_{jk} F(U_k(t)) \right] dt + d\tilde{W}_j(t) \quad (5)$$

Here $\tilde{W}_j(t) = \sum_{k=1}^P w_{jk} \sigma_k W_k(t)$ so that

$$\begin{aligned} \langle d\tilde{W}_j(t) \rangle &= 0, \langle d\tilde{W}_j(t) d\tilde{W}_k(t) \rangle \\ &= \left[\sum_j C_{kl} w_{jl} w_{kf} \sigma_l \sigma_f \right] dt. \end{aligned} \quad (6)$$

On the other hand, in the limit $\tau \rightarrow 0$, we obtain a stochastic *activity-based* model

$$\begin{aligned} \hat{\tau} dA_j(t) &= \left[-A_j(t) + F\left(\sum_k w_{jk} A_k(t)\right) \right] dt \\ &+ \sigma_j dW_j(t). \end{aligned} \quad (7)$$

Master Equation Formulation

An alternative approach to incorporating noise into the population firing rate has been developed in terms of a jump Markov process (Buice and Cowan 2007; Bressloff 2009, 2010; Buice et al. 2010). Such a description is motivated by the idea that each local population consists of a discrete number of spiking neurons and that finite-size effects are a source of intrinsic rather than extrinsic noise (Soula and Chow 2007; El Boustani and Destexhe 2009). The stochastic output activity of a local population of N neurons is now expressed as $A_j(t) = N_j(t)/(N\Delta t)$ where $N_j(t)$ is the number of neurons in the j th population that fired in the time interval $[t - \Delta t, t]$, and Δt is the width of a sliding window that counts spikes. Suppose that the discrete stochastic variables $N_j(t)$ evolve according to a one-step jump Markov process:

$$\begin{aligned} N_j(t) &\rightarrow N_j(t) \pm 1 \\ &: \text{transition rate } \Omega_{\pm j}(t), \end{aligned} \quad (8)$$

in which $\Omega_j^{\pm}(t)$ are functions of $N_j(t)$ and $U_j(t)$ with $U_j(t)$ evolving according to the integral eq. 2 or its differential version (4). Thus, synaptic coupling

between populations occurs via the transition rates. The transition rates are chosen in order to yield a deterministic rate-based model in the thermodynamic limit $N \rightarrow \infty$. One such choice is

$$\Omega_j^+(t) = \frac{N\Delta t}{\hat{\tau}} F(U_j(t)), \quad \Omega_j^-(t) = N_j(t)\hat{\tau}. \quad (9)$$

A further simplification is obtained in the limit $\tau \rightarrow 0$, since the continuous variables $U_j(t)$ can be eliminated to give a pure birth-death process for the discrete variables $N_j(t)$. Let $P(\mathbf{n}, t) = \text{Prob}[N(t) = \mathbf{n}]$ denote the probability that the network of interacting populations has configuration $\mathbf{n} = (n_1, n_2, \dots, n_P)$ at time t , $t > 0$, given some initial distribution $P(\mathbf{n}, 0)$. The probability distribution then evolves according to the birth-death master eqs. 8–10

$$\begin{aligned} \frac{dP(\mathbf{n}, t)}{dt} = & \sum_{\alpha} \left[(\mathbb{E}_{\alpha} - 1) \left(\Omega_{\alpha}^-(\mathbf{n}) P(\mathbf{n}, t) \right) + (\mathbb{E}_{\alpha}^{-1} - 1) \left(\Omega_{\alpha}^+(\mathbf{n}) P(\mathbf{n}, t) \right) \right], \\ & (10) \end{aligned}$$

where $\Omega_j^+(\mathbf{n}) = (N\Delta/\hat{\tau}) F\left[\sum_k w_{jk} n_k / (N\Delta t)\right]$, $\Omega_j^-(\mathbf{n}) = n_j / \hat{\tau}$ and $\mathbb{E}_j$ are translation operators: $\mathbb{E}_j^{\pm 1} F(\mathbf{n}) = F(\mathbf{n}_{j\pm})$ for any function F with $\mathbf{n}_{j\pm}$ denoting the configuration with n_j replaced by $n_j \pm 1$. Equation 10 is supplemented by the boundary conditions $P(\mathbf{n}, t) = 0$ if $n_j = N + 1$ or $n_j = -1$ for some j . The birth-death master eq. 10 has been the starting point for a number of studies of the effects of intrinsic noise on neural fields, which adapt various methods from the analysis of chemical master equations including system-size expansions and path integral representations (Buice and Cowan 2007; Bressloff 2009; Buice et al. 2010). For large N the master equation can be approximated by a Langevin equation with multiplicative noise and thus reduces to the previous class of stochastic neural field model (Bressloff 2009).

Continuum Limit

A stochastic neural field equation can be obtained from either formulation by taking an appropriate

continuum limit. For simplicity, we will focus on the simplest stochastic rate model given by Eqs. 1 and 4. The continuum limit of Eq. 4 proceeds heuristically as follows. First, set $U_j(t) = U(j\Delta d, t)$, $A_j(t) = A(j\Delta d, t)$, and $w_{jk} = \rho\Delta d w(j\Delta d, k\Delta d)$ where ρ is a synaptic density and Δd is an infinitesimal length scale. Taking the limit $\Delta \rightarrow 0$ and absorbing ρ into w gives

$$\tau dU(x, t) = \left[-U(x, t) + \int_{-\infty}^{\infty} w(x-y) A(y) dy \right] dt. \quad (11)$$

We also assume that the noise strength $\sigma_j = \sigma/\sqrt{\Delta d}$ and define $w_j(t)/\sqrt{\Delta d} = w(j\Delta d, t)$. Taking the limit $\Delta d \rightarrow 0$ in Eq. 1 gives

$$\begin{aligned} \hat{\tau} dA(x, t) = & [-A(x, t) + F(U(x, t))] dt \\ & + \sigma dW(x, t) \end{aligned} \quad (12)$$

With

$$\begin{aligned} \langle dW(x, t) \rangle &= 0, \quad \langle dW(x, t) dW(y, t) \rangle \\ &= C(x-y) dt, \end{aligned} \quad (13)$$

where we have assumed that C_{ij} depends on $|i-j|$. In the limit $\hat{\tau} \rightarrow 0$ we obtain a stochastic version of a voltage-based neural field equation, namely,

$$\begin{aligned} \tau dU(x, t) = & \left[-U(x, t) + \int_{-\infty}^{\infty} w(x-y) F(U(y, t)) dy \right] dt \\ & + \sigma d\tilde{W}(x, t) \end{aligned} \quad (14)$$

with $\langle d\tilde{W}(x, t) \rangle = 0$

$$\begin{aligned} \langle d\tilde{W}(x, t) d\tilde{W}(y, t) \rangle = & \\ dt \int_{-\infty}^{\infty} C(Z-Z') w(x-z) w(y-z') dz dz'. \end{aligned} \quad (15)$$

Similarly, in the limit $\tau \rightarrow 0$ we have a stochastic version of an activity-based neural field equation

$$\begin{aligned} \hat{\tau} dA(x, t) = & \left[-A(x, t) + F\left(\int_{-\infty}^{\infty} w(x-y) A(y, t) dy\right) \right] dt \\ & + dW(x, t). \end{aligned} \quad (16)$$

From a numerical perspective, any computer simulation would involve discretizing space and then solving a time-discretized version of the resulting stochastic differential equation. On the other hand, in order to investigate analytically the effects of noise on spatiotemporal dynamics, it is more useful to work directly with stochastic neural fields. One can then adapt various PDE methods for studying noise in spatially extended systems (Sagues et al. 2007).

Applications

One application of stochastic neural field theory is to binocular rivalry waves (Bressloff and Webber 2012b). The basic model consists of two voltage-based excitatory neural fields of the form (14), which represent right and left eye networks, respectively. The neural fields mutually inhibit each other and also undergo some form of slow adaptation such as synaptic depression. It can be shown that the deterministic model supports a composite traveling front, in which the activity of one network advances while the other retreats – this represents the spatiotemporal switch in eye dominance that has been observed experimentally (Wilson et al. 2001). When multiplicative extrinsic noise is added to the model, one finds that the noise generates two distinct phenomena that occur on different time scales: a diffusive-like displacement of the binocular rivalry wave from its uniformly translating position at long time scales and fluctuations in the wave profile around its instantaneous position at short time scales. Moreover, one can use perturbation methods to calculate the diffusion coefficient characterizing the wandering of the front (Bressloff and Webber 2012b).

Another application of stochastic neural field theory is to modeling spontaneous cortical activity in vitro and in vivo (Beggs and Plenz 2004; Plenz and Thiagarajan 2007). Buice and Cowan (Plenz and Thiagarajan 2007) have used path integral methods and renormalization group theory to establish that a stochastic neural field model based on a continuum version of a birth-death master equation belongs to the universality class of directed percolation and consequently exhibits

power law behavior consistent with measurements of neuronal avalanches in vitro and in vivo (Beggs and Plenz 2004; Plenz and Thiagarajan 2007).

Noise enhancement of weak subthreshold signals

Definition

Originally discovered in climate data (Nicolis and Nicolis 1981; Nicolis 1982), the phenomenon of stochastic resonance occurs when an intermediate (i.e., neither too large nor too small) amount of noise enhances the transmission of a weak periodic signal (McNamara and Wiesenfeld 1989). The signal is “weak” in the sense that, in the absence of noise, it is below the threshold of detection. Low-amplitude added noise contributes jitter to the weak periodic signal but is not sufficient to push the signal over the detection threshold. Large-amplitude noisy input, in contrast, adds so much jitter that, while the weak signal plus noise does often exceed the threshold, the signal is not separable from the noise (Jung and Hänggi 1991; Dykman et al. 1992). An intermediate-amplitude noisy input allows the weak signal

plus noise to cross the detection threshold sufficiently often that, upon sampling the threshold-crossing events, the original periodicity of the weak signal can be detected. The signal-to-noise ratio exhibits a characteristic peak when plotted as a function of the input noise amplitude. For comprehensive reviews of the phenomenon, see Moss and Wiesenfeld (1995), Wiesenfeld and Moss (1995), and Gammaitoni et al. (1998).

Detailed Description

Because of the periodic firing of neurons (and the periodicity of many other biological rhythms), biological physicists and neuroscientists have searched for evidence of stochastic resonance in various neural domains. Stochastic resonance has indeed been observed in a wide range of neural systems in many species, from the crayfish mechanosensory system (Pei et al. 1996) to the human visual system (Simonotto et al. 1997).

One of the areas where a stochastic resonance-like effect has been investigated with most relevance to the clinical treatment of human disorders has been that of balance control. A pioneering set of studies in this area was initiated by James Collins’s research group in the Center for BioDynamics at Boston University. In a 2002 paper in *Physical Review Letters* (Priplata et al. 2002), they tested a feedback system in which the (roughly periodic) postural sway of humans during quiet standing could be significantly reduced by adding a small amount of mechanical noise to the subjects’ feet. Subjects stood on a platform that contained actuators to provide input noise, with the frequency range and amplitude of the noise controlled by the experimenters. The authors suggested that this approach could lead to the development of vibrating shoe insoles that could enhance balance in the elderly and successfully implemented this idea (Priplata et al. 2003). Noise stimulation applied directly to the tibialis anterior muscle can also improve performance during a challenging balance task in healthy young adults (Severini and Delahunt 2018). Application of mechanical noise to ankle muscle tendons has been shown to improve postural control (Borel

and Ribot-Ciscar 2016). Other studies have shown that stochastic vestibular stimulation can improve locomotor stability and balance in healthy subjects (Goel et al. 2015; Mulavara et al. 2015; Wuehr et al. 2016a, 2018) as well as in patients with bilateral vestibulopathy (Iwasaki et al. 2014, 2018; Wuehr et al. 2016b). Whole-body vibration has also been tested as a means of enhancing balance in the elderly (Rogan et al. 2015) and in subjects with balance disability and a history of falls (Rogan et al. 2014). Yet another recent study implemented a more colloquially literal version of “noise” showing that auditory white noise can reduce age-related fluctuations in balance (Ross et al. 2016).

The underlying dynamics of this process can be related to the familiar task of trying to balance a meter stick on a finger or palm. The task proves far easier when one’s hand is moving underneath the stick. Milton et al. (2009a) combined these two processes in a study of stick balancing by subjects on a vibrating platform and interpreted the vibration-enhanced balance control as a “time-delayed drift and act” effect. In this experiment, the subjects stood on a vibrating platform that produced vertical vibrations in their fingertips. These vibrations reduced the amplitude of fluctuations (in relative horizontal plane position) between the fingertip and the tip of the stick. A nonlinear dynamics-based exploration of the phenomenon can be found in Milton et al. (2009b).

The neural pathways involved in noise-enhanced human balance have not yet been completely elucidated. However, stochastic resonance has already been applied in a variety of clinical situations. A pilot study has been conducted to explore the possibility of using whole-body vibration to enhance chair rising in the elderly (Rogan et al. 2012) and as a possible therapy for Parkinsonian tremor (Kaut et al. 2011). Vibration-enhanced stability studies have been conducted in subjects with ankle instability (Ross and Guskiewicz 2006; Ross 2007; Ross et al. 2013) and with osteoarthritic knees (Collins et al. 2012) and to reduce musculoskeletal stress in metal manufacturing workers (Burger et al. 2012). Stochastic resonance has also been

recently explored in the context of enhancing sensorimotor performance with noise added as a tactile stimulus to the subjects’ fingers (Mendez-Balbuena et al. 2012).

Perhaps one of the most intriguing clinical applications of stochastic resonance is in the area of hearing impairment. After showing that the addition of actual auditory noise to a vowel coded in a cochlear implant enhanced the neural evoked response Morse and Evans (1996, 1999a, b) and Morse and Roper (2000) suggested that stochastic resonance techniques could be applied in the design of cochlear implants. The design of stochastic resonance-based cochlear implants become an active area of research in the early 2000s (Zeng et al. 2000; Chatterjee and Robert 2001; Stocks et al. 2002; Benham and Zeng 2003; Hong and Rubinstein 2003; Rubinstein and Hong 2003; Chatterjee and Oba 2005). It has been suggested that stochastic resonance may play a role in enhancing unimpaired hearing as well, with the Brownian motion of cochlear fluids providing a natural source of noise for the optimization of hair cell response (Ehrenberger et al. 1999). Among the most recent developments in the study of stochastic resonance in normal sound processing, Martignoli et al. (2013) showed that pitch sensation involves stochastic resonance. Regarding hearing pathology, Krauss et al. (2016) have suggested that stochastic resonance may mediate the upregulation of internal noise after hearing loss, leading to tinnitus. The coming decade is sure to bring further developments in the understanding of the role of stochastic resonance in both normal and pathological sensory processing.

Definition

A stochastic simulator for reaction-diffusion systems is a computer simulation tool that uses the Monte Carlo method to generate the time evolution of a spatially inhomogeneous chemically reacting system. The main types of stochastic simulators used in neuroscience are particle based and population based. The stochastic simulation algorithm (SSA) is a population-based method that numerically simulates the time evolution of a well-stirred chemically reacting system in thermal equilibrium by defining the state of the system to be the integer numbers of molecular populations. The SSA has been extended to incorporate diffusion, usually called the inhomogeneous SSA (ISSA), by dividing the spatial domain into a collection of well-stirred subvolumes and treating diffusion between neighboring subvolumes as a set of first-order reactions. This entry focuses on stochastic simulators that use the inhomogeneous SSA.

Detailed Description

The small numbers of molecules in various spatial compartments of biological cells give rise to stochastic variations in intracellular microdomains. These stochastic variations affect the behavior of biochemical network components, such as oscillators, switches, and positive and negative feedback loops, and play a significant role in the spatiotemporal activity and behavior of cells, such as cell differentiation, gene regulatory networks, and synaptic plasticity (e.g., reviews by Kotaleski and Blackwell 2010; Bhalla 2014; Harton and Batchelor 2017; Gonze et al. 2018). In addition, the long thin dendrites characteristic of neurons produce spatial gradients and diffusional movement of molecules. Computer simulation enables computational investigation of the stochastic and spatial effects on neuron activity that may be difficult to monitor in detail experimentally (Boulianne et al. 2008), thereby providing a more amenable investigative platform to test hypotheses and gain further insights.

Traditionally, computer simulation of biochemical networks has involved deterministic approaches that represent each molecule population as a continuous-valued concentration. By ignoring spatial heterogeneity, systems of ordinary differential equations can be used to describe the time evolution of concentrations. On the other hand, when the concentrations are spatially heterogeneous, systems of partial differential equations are used. Deterministic models and simulations are valid in the thermodynamic limit of large numbers of molecules and describe the average behavior of the modeled system. However, when molecule populations are small, discrete numbers of molecules rather than mean behavior need to be examined, and stochastic fluctuation in molecule numbers influences the time evolution of the system.

Stochastic simulation methods are categorized as either spatial or nonspatial methods (Takahashi et al. 2005). Nonspatial stochastic simulators (Alves et al. 2006) assume that the system to be modeled is well-stirred, that is, nonreactive collisions between molecules occur much more frequently than reactive collisions such that the

molecules become uniformly randomly distributed in thermal equilibrium (Gillespie 1976, 2006). However, spatial heterogeneity is observed experimentally in neurons for many molecular species, implying that spatial stochastic simulations are required to accurately capture signaling pathway activity and interactions in neurons (Bhalla 2004; Lemerle et al. 2005; Takahashi et al. 2005).

Spatial stochastic simulation methods are further categorized as particle-based or population-based (also known as voxel-based or subvolume-based) methods (Takahashi et al. 2005). Recent, particle-based spatial stochastic simulators use a variety of methods, including molecular dynamics, Brownian dynamics (see entry ► [“Particle-Based Stochastic Simulators”](#)), Green’s function reaction dynamics, and lattice-based approaches, to model the system at a single particle detail (Tolle and Le Novère 2010; Stefan et al. 2014; Andrews 2017; Sbailò and Noé 2017; Ekimoto and Ikeguchi 2018; Sokolowski et al. 2019). With these simulators, the location and reactions of individual molecules are tracked providing the time evolution of the system state at microscopic detail. Two Brownian motion simulators, ► [“MCell”](#) and Smoldyn, have been used most commonly to study signaling pathways in neurons. Rule-based modeling is a recent advanced alternative to specification of the almost countless number of possible reactions in multi-state molecules (Colvin et al. 2010; Ibrahim et al. 2013). Rule-based modeling allows specification of families of reactions (e.g., phosphorylation of multiple sites), and then the simulator implements the particular reactions as needed. Particle-based methods offer high spatial resolution; however population-based stochastic simulation methods are computationally more efficient than particle-based simulation methods (Dobrzyński et al. 2007; Andrews et al. 2010). Population-based spatial stochastic simulators subdivide the simulation volume into a collection of well-stirred subvolumes, and reactions are simulated in each subvolume by using a variant of Gillespie’s stochastic simulation algorithm (see entry ► [“Gillespie Algorithm for Biochemical Reaction Simulation”](#); Gillespie 2006), whereas diffusions

between neighboring subvolumes are simulated as a set of first-order reactions. Population-based simulators keep track of the population number of each molecule species in each subvolume, thereby providing the time evolution of the system state at mesoscopic detail. For both population-based and particle-based simulations, several simulation runs are made from the same initial condition with different random seeds for analysis of the probability distribution, average, and/or variance of the system trajectories.

Here we categorize population-based spatial stochastic simulation methods by the numerical simulation approach. We first briefly explain the extension of Gillespie's stochastic simulation algorithm (SSA) for well-stirred systems to spatial or inhomogeneous systems with well-stirred (homogeneous) subvolumes. We then describe stochastic simulation methods that utilize an exact ISSA approach. Next, we describe stochastic simulation methods that utilize approximate SSA approaches to ameliorate the heavy computational burden placed by the exact approach. We conclude with discussion of limitations and advantages of the current population-based spatial stochastic simulation methods.

Spatial Extension of Gillespie's Stochastic Simulation Algorithm

Gillespie's SSA (see entry ► "Gillespie Algorithm for Biochemical Reaction Simulation") is extended to include diffusion by relaxing the well-stirred requirement. For the inhomogeneous SSA (ISSA), the system volume Ω is partitioned into Q subvolumes $\{V_1, \dots, V_Q\}$, each of which is assumed to be well-stirred. There are N molecular species $\{S_1, \dots, S_N\}$ that are involved in M chemical reaction channels $\{R_1, \dots, R_M\}$ in each subvolume, and each molecular species has a diffusion coefficient D_i ($i = 1, 2, \dots, N$) greater than or equal to zero. The state vector $X_k(t) = (X_{1k}(t), \dots, X_{Nk}(t))$ denotes the number of molecules of S_i ($i = 1, 2, \dots, N$) in subvolume V_k ($k = 1, 2, \dots, Q$) at time t . Then $X(t) = (X_1(t); \dots; X_Q(t))$ denotes the Q by N state matrix of the system at time t . N molecular species in each subvolume V_k are involved in M chemical

reaction channels $\{R_{1k}, \dots, R_{Mk}\}$ and $N \cdot B_k$ diffusion channels $\{R_{ikl}^d\}$ where B_k is the number of V_k 's neighboring subvolumes and l denotes the index of each neighboring subvolume of V_k . Each reaction channel R_{jk} ($j = 1, 2, \dots, M$; $k = 1, 2, \dots, Q$) is characterized by a propensity function a_{jk} and the state change vector v_j : Given the current state of the system $x = X(t)$, $a_{jk}(x)dt$ gives the probability that an R_{jk} reaction will occur in the next time interval $[t, t + dt)$ in subvolume V_k . The state change vector v_j gives the change in the molecule populations produced by one R_{jk} reaction such that $x_k \rightarrow x_k + v_j$. Diffusive transfers of a molecule of species S_i from a subvolume V_k to a neighboring subvolume V_l are treated as unimolecular reactions, $S_{ik} \rightarrow S_{il}$ (Baras and Mansour 1996; Stundzia and Lumsden 1996). Each diffusion channel R_{ikl}^d is characterized by a propensity function $\kappa_{ikl}x_{ik}$ and state change matrix $E_i^l - E_i^k$, where κ_{ikl} is a constant proportional to the diffusion rate constant D_i (e.g., when V_k and V_l are both cuboids with side length u , $\kappa_{ikl} = D_i/u^2$), $E_i^l - E_i^k$ gives the change in the molecular populations produced by one R_{ikl}^d diffusion, and E_i^k denotes the Q by N matrix whose entries are all zero except for the entry (k, i) . Therefore, whereas Gillespie's SSA has M total reaction channels in the system volume Ω , the ISSA has up to $M \cdot Q + \sum_{k=1}^Q (N \cdot B_k)$ reaction channels in the system volume Ω that is subdivided into Q subvolumes. Note that the total number of diffusive transfer reaction channels is less than $\sum_{k=1}^Q (N \cdot B_k)$ when the diffusion coefficient of one or more molecule species S_i ($i = 1, 2, \dots, N$) is zero.

Starting from some initial conditions, the ISSA proceeds by generating the time step τ to the next reaction and determining which reaction occurs in that next time interval and then effecting the reaction by updating the time and the state matrix. Gillespie gave two implementations of his SSA: the direct method and the first-reaction method (Gillespie 1977).

With the first-reaction method, the next time step τ and the next reaction μ are determined by generating up to $M \cdot Q + \sum_{k=1}^Q (N \cdot B_k)$ random numbers r_{jk} from the uniform distribution in the unit interval and calculating

$$\tau_{jk} = \frac{1}{a_{jk}(x)} \ln \frac{1}{r_{jk}} \quad (1)$$

and

$$\tau_{ib_k} = \frac{1}{K_{ikl}x_{ik}} \ln \frac{1}{r_{ib_k}} \quad (2)$$

and then selecting τ to be the smallest and μ to be the reaction R_{jk} or diffusion R_{ikl}^d of the smallest τ . With the direct method, a single time step τ is randomly chosen from an exponential distribution with parameter equal the sum of propensity functions, and then the reaction identity is determined using a second random number. The ISSA generates a trajectory of the corresponding reaction-diffusion master equation (RDME), which describes the time evolution of the spatially varying probability density functions of molecule populations (Baras and Mansour 1996; Isaacson and Peskin 2006).

Exact Spatial (Inhomogeneous) Stochastic Simulation Methods

Several extensions of the exact stochastic simulation algorithm for spatially inhomogeneous conditions (also known as inhomogeneous stochastic simulation algorithm or ISSA) have been used to study signaling pathways in neurons. STEPS (see entry ► “[STEPS: STochastic Engine for Pathway Simulation](#)”; Hepburn et al. 2012) extends the direct method and improves computational efficiency using a composition and rejection method (Slepoy et al. 2008) to optimize propensity value update and to determine the next reaction at each time step. STEPS also uses tetrahedral meshes instead of cuboids, which allows STEPS to simulate more realistic geometries. STEPS has been used to investigate the interaction between a positive feedback loop and glutamate receptor trafficking in cerebellar LTD in a single spine (Antunes and De Schutter 2012). More recently STEPS has been extended with a python interface to facilitate geometry specification, visualization, and analysis of simulation output (Chen and De Schutter 2014). To enhance interaction between neuron membrane potential and signaling pathways, STEPS recently added an algorithm for

calculating changes in electrical potential due to ionic currents and calculation of voltage-dependent gating variables (Hepburn et al. 2013, 2016). URDME (Drawert et al. 2012) uses the next subvolume method (Elf and Ehrenberg 2004) with unstructured tetrahedral meshes. URDME has been further developed to provide a python interface and a cloud computing interface (Drawert et al. 2016b). MOOSE is a general-purpose, compartmental-based neuron simulation tool with a Python interface that facilitates modeling of electrical potential and signaling pathways (Ray and Bhalla 2008). The reaction-diffusion systems can be solved either deterministically or using voxel-based exact stochastic simulation and can interact with the electrical potential, e.g., calcium influx is controlled by the electrical potential and initiates a cascade of reactions. A recent model of signaling pathways connects calcium influx to activation of the mitogen-activated protein kinase (MAPK) to modulation of ionic channels (Bhalla 2017). Simulations showed how the neuron could distinguish the sequences of synaptic inputs.

An important new direction in model and simulator development is including the role of crowding and volume exclusion. In most simulators, molecules are modeled as points that have no volume; thus the number of molecules in the simulated structure is limitless. Reality contrasts sharply with this assumption. Whether using population- or particle-based methods, molecules occupy a small volume of space, which decreases the “empty” space available for diffusion. Recent research has demonstrated that packing a large number of molecules into a small space can reduce diffusion rates. If the molecules crowded together have the ability to react, such crowding can enhance reaction rates, whereas if the molecules do not react, the impeded diffusion can reduce reaction rates. The most recent release of Smoldyn, a particle simulator, allows modeling of crowding caused by excluded volume (Andrews 2017), as does PyURDME (Golkaram et al. 2016), the population simulator. Research on gene expression using the latter showed that crowding reduces noise in gene expression by limiting the diffusion of transcription factors.

Additional simulators or algorithms have been developed to facilitate simulation of crowding (Schöneberg and Noé 2013; Meinecke 2017; Hoffmann et al. 2019), e.g., by taking into account both molecule radius and density to modify the diffusion propensity (Cianci et al. 2017). A recent publication investigated how synaptic domains form despite stochastic turnover and diffusion of molecules (Li et al. 2017). The stochastic algorithm implements the spatial next reaction method (Elf et al. 2003), modified to account for crowding by reducing rate constants of reaction and diffusion as receptor numbers increase. This model predicts that receptors adjacent to synaptic domains are more likely to be removed from the cell membrane than the centrally located receptors, which is consistent with experimental observation.

Another new research direction is being driven by a key outcome of signaling pathway activation, namely, producing changes in cell morphology. For example, during induction of synaptic plasticity, the size of dendritic spines may grow or shrink. During neuronal development, dendrites and axons are extended. The change in compartment size may form a feedback loop through its influence on molecule concentration. Recently, two simulators or algorithms have begun to address changes in morphology. URDME has been extended with the ability to include a moving boundary (Drawert et al. 2016c), and compartment sizes can change during MOOSE simulations, also.

Spatial stochastic simulations, even using voxel-based methods, are computationally intensive, and the simulation of large systems is slow. One solution to improve simulation speed of the ISSA is to use time-dependent propensity functions to account for the change in propensity that would be caused by continuous diffusion (Fu et al. 2014), thereby reducing the typically overwhelming number of diffusion steps. Another method is to parallelize the algorithm, which has been done with STEPS (Hepburn et al. 2016; Chen and De Schutter 2017). Some algorithms, such as Lattice Microbes (Roberts et al. 2013; Hallock et al. 2014), are written directly for parallel simulation and utilize NVIDIA graphics processing units

(GPUs). Even particle simulators are being implemented on GPUs for enhanced computational efficiency (Dematté 2012). Another approach is to provide a simulation service on a high-performance computing platform. Typically these simulation services provide integrated development environments and allow selection of the simulation algorithm from among a variety of deterministic and stochastic solvers (Drawert et al. 2016a; Blinov et al. 2017).

Approximate Spatial Stochastic Simulation Methods

A more common approach to improving computational efficiency of spatial stochastic simulation is to use approximate algorithms. For simulating well-stirred systems, a generally applicable approximate method is the nonnegative Poisson τ -leaping method (Cao et al. 2005; Yates and Burrage 2011). This method advances the state of the system by the largest value of the leap time τ while simultaneously allowing multiple reaction events to occur and satisfying the leap condition (Gillespie 2001; Gillespie and Petzold 2003), which states that no propensity function is likely to change its value by a significant amount during $[t, t + \tau)$. In τ -leaping the state vector is updated as

$$X(t + \tau) \doteq x + \sum_{j=1}^M P_j(a_j(x)\tau) v_j \quad (3)$$

where $P_j(a_j(x)\tau)$ is a statistically independent Poisson random variable. The leap condition specifies τ and bounds the relative change in each propensity function $a_j(x)$ during the leap. An additional control strategy is implemented to prevent any of the population of reactant species from becoming negative due to the unboundedness of the Poisson random numbers (Cao et al. 2005). When τ is both small enough to satisfy the leap condition and large enough such that the expected number of firings of each reaction channel R_j during τ is much greater than one, the τ -leaping strategy is equivalent to the chemical Langevin equation (Gillespie 2007).

The τ -leaping method has been extended to spatial stochastic simulations using a fixed leap

time (Blackwell 2006; Oliveira et al. 2010). At each time step, NeuroRD determines the number of reactions and diffusions from tabulated binomial distributions when the number of reactants in a subvolume is below a threshold, otherwise it uses Poisson or Gaussian distributions. It distributes diffusing molecules from a subvolume among its neighbors with multinomial probabilities. NeuroRD has been used to investigate the role of anchoring proteins in synaptic plasticity (Kim et al. 2011; Oliveira et al. 2012). It has also been used to investigate how different spatiotemporal patterns of synaptic input determine the direction of synaptic plasticity (Kim et al. 2013). Because of the computational efficiency of NeuroRD, it has been used to simulate over a hundred species and over a hundred reactions in a dendrite with multiple spines.

The problem with a fixed leap time is the possibility of producing negative populations or violating the leap condition. Thus, several spatial τ -leap algorithms dynamically select the leap time (Marquez-Lago and Burrage 2007; Rossinelli et al. 2008). However, selecting the next leap time τ requires a larger computational overhead (Cao et al. 2006; Chatterjee and Vlachos 2007) than selecting the next event time with the exact algorithm. The added computational overhead accumulates especially when the leap time τ is repeatedly rejected to prevent potential negative populations and the system must evolve following the exact algorithm, which sometimes makes a τ -leaping simulation slower than an exact simulation (Koh and Blackwell 2011).

Most variants of the nonnegative τ -leap algorithm advance every reaction and diffusion channel by the same τ , which constrains the leap time especially for stiff systems. A common solution, discussed below, is to partition the system into two or more subsystems, e.g., reaction versus diffusion and large versus small populations, and use different methods for different subsystems. However, partitioning is problematic when population size or reaction speed forms a continuum and when the transient events common in neurons require frequent repartitioning. A recent solution to this problem is asynchronous τ -leaping (Jedrzejewski-Szmek and Blackwell 2016), in

which each reaction or diffusion event is simulated either using its own leap time or using an exact simulation event depending on its propensity. This improves computational efficiency without sacrificing accuracy and avoids the need for the user to partition the system.

Despite the problems with partitioning the system, a common approach for enhancing computational efficiency is to create hybrid simulation algorithms, in which the system is partitioned into subsystems, with one system using an exact stochastic simulation and the other system using either approximate stochastic simulation or deterministic simulation. A common hybrid approach partitions the system into reaction and diffusion subsystems, in part because diffusion often limits the leap time, and then various methods are used to accelerate diffusion. The hybrid τ -leaping method (Rossinelli et al. 2008) simulates diffusion deterministically, and the time step for simulating reactions stochastically is chosen with the τ -leaping method. The multinomial simulation algorithm (Lampoudi et al. 2009) simulates diffusion by distributing diffusing molecules from a subvolume among its neighbors with multinomial probabilities until the time to the next reaction event is reached while simulating reactions with the direct method. The adaptive hybrid method (Ferm et al. 2010) simulates reactions with the next subvolume method (Elf and Ehrenberg 2004) while simulating diffusion in three different ways – exact, τ -leaping, and deterministic – depending on the number of diffusing molecules. The spatial direct method with gradient-based diffusion (Koh and Blackwell 2012) uses the direct method but approximates diffusion processes by using diffusion propensities that are based on the net movement of molecules from higher to lower concentration gradients rather than sampling all diffusion events regardless of local concentration gradients. This method also allows the user to control the degree of exactness in simulation with a control parameter. Several algorithms use variants of partial differential equations for the diffusion part. One algorithm uses the deterministic solution (partial differential equation) for diffusion where particle numbers are high, voxel-based stochastic simulation where

the numbers are low, and both methods in an intermediate or overlap region (Harrison and Yates 2016). In the overlap region, the deterministic solution is interpreted as a probability, and the boundary condition ensures that the flux is the same for the PDE and voxel-based simulation. Another algorithm (Kim et al. 2017) simulates the reaction subsystem using an adaptive leap algorithm and simulates the diffusion subsystem using a stochastic Crank-Nicolson solver, which is a type of stochastic partial differential equation. This operator splitting is not without numerical accuracy errors dependent on the time step (Hellander et al. 2014); thus using adaptive time step methods can provide gains in both accuracy and computational efficiency. Note that more recent hybrid algorithms have been developed for efficient particle simulation of diffusion (Donev et al. 2018; Smith and Yates 2018), but their discussion is beyond the scope of this article.

An alternative set of hybrid approaches ignores whether events are reaction versus diffusion and instead partitions based on propensity of the reaction. For example, one algorithm partitions the system into fast and slow subsets and then uses the next subvolume method for slow events and spatial tau leaping for fast events (Strehl and Ilie 2015). The spatial partitioned leaping algorithm (Iyengar et al. 2010) calculates the next leap time τ with the nonnegative Poisson τ -leaping method. It then classifies each reaction and diffusion in the system into one of the four categories – exact-stochastic, Poisson, Langevin, and deterministic – and advances the system based on τ and the category. In all of the above cases, partitioning is done manually, which requires expert knowledge about the system to be partitioned. A solution to this problem (Hellander et al. 2017) not only automates the partitioning but allows for dynamic partitioning. In contrast to most hybrid methods, the two subsystems are simulated using either a particle algorithm or a new voxel-based method called the next particle method.

Even with the speedups obtained from approximate methods, stochastic simulation is still computationally intensive; thus these methods also are being accelerated using parallel

simulation methods. A hybrid method known as the Gillespie multiparticle method has been parallelized for GPUs (Vigelius et al. 2011), with $\sim 10\times$ increase in speed over the non-parallelized version, which itself is faster than the exact methods such as the next subvolume method. A spatial tau-leaping algorithm has been parallelized by implementing each subvolume on a different processor (D'Agostino et al. 2014). This algorithm has the further advantage of implementing a form of crowding, by modifying propensity functions according to particle density.

Advantages and Challenges

The increase in computational power has spurred an increase in development of spatial stochastic simulators and the use of spatial stochastic simulation to make experimental predictions. Population-based spatial stochastic simulators are especially advantageous in allowing quantitative investigation at a mesoscopic detail, corresponding to experiments that measure molecule concentration in dendritic spines (e.g., Hedrick et al. 2016). On the other hand, particle simulations are critical for quantitative investigation at the microscopic detail corresponding to super-resolution microscopy experiments providing dynamic information on single particle location (e.g., MacGillavry and Blanpied 2013). The mesoscopic approximation by subdividing the system volume into subvolumes has the advantage of computational efficiency, but can also be a limitation in terms of accuracy or the ability to use rule-based approaches (see Blinov et al. 2017).

The subdivision of the system volume into subvolumes for mesoscopic simulation can be problematic. The approach of reducing subvolume size until they are small enough to satisfy the assumption of well-stirred is not possible, because if the subvolume size approaches the size of molecules, then reaction propensities are inaccurate (Hellander et al. 2012). At the same time, if the subvolume sizes are too large, they violate the well-stirred requirement and may not accurately capture concentration gradients observed, e.g., within single spines. Thus, when

the subvolume sizes are either too small or too large, simulations are inaccurate (Erban and Chapman 2009; Isaacson 2009; Hellander et al. 2017). For the well-stirred assumption to be physically valid, the width of the subvolume must satisfy $\tau_R \gg \tau_D$, where τ_R and τ_D denote the typical time interval between reaction events and the typical time interval between diffusion events, respectively, and also that the width must be less than the reactant correlation length, which is difficult to predict (Isaacson 2009).

Along with the increase in computational power, which should permit ever more accurate simulations, biological complexity appears to be increasing, requiring increasing details regarding molecule interactions. Thus, simulators that allow rule-based modeling or account for molecule crowding are increasing. For a systematic investigation of cellular processes spanning different spatial and temporal scales at various levels of detail, a remaining challenge is for a simulator to seamlessly and accurately transition among microscopic, mesoscopic, and macroscopic levels of detail, as some recent simulators have introduced (Smith and Yates 2018). Meanwhile, population-based spatial stochastic simulators provide a good balance between sufficient stochastic and spatial details in simulation output and practical simulation speed.

Subthalamopallidal Loop and Oscillations

David Terman

Department of Mathematics, The Ohio State University, Columbus, OH, USA

Definition

The subthalamopallidal loop consists of reciprocally connected glutamatergic neurons of the subthalamic nucleus (STN) and GABAergic neurons of the external globus pallidus (GPe). The STN and GPe are both nuclei within the basal ganglia (BG). Oscillations correspond to regularly recurring spiking activity of a neuronal system.

Detailed Description

Activity Patterns in the Subthalamopallidal Network

During quiet wakefulness, GPe neurons maintain mean firing rates in excess of 40 Hz, while STN neurons average about 20 Hz (Wilson 2010). The neurons fire without rhythm, and there is rarely synchrony between the spontaneous discharges of different neurons in the BG of neurologically normal subjects (Rubin et al. 2012). During voluntary or passive movement, STN and GPe neurons display intricate spatiotemporal changes in activity, which relate in a complex manner to motor activity. During movement, activity is rarely correlated but it is highly structured, so that there is precise somatotopic specificity (Bevan et al. 2002).

In Parkinson's disease, rhythmic bursting activity at 4–10 Hz and 15–30 Hz is observed in the STN, GPe, and other parts of the basal ganglia (Bevan et al. 2002). This activity is often correlated within and between nuclei: Neurons that are close to each other within areas located

throughout the BG and the BG-receiving areas of the thalamus and the cortex tend to fire in synchrony (Rubin et al. 2012).

Microcircuitry of the Subthalamopallidal Network

The subthalamopallidal loop forms an excitatory–inhibitory network: GPe neurons make inhibitory connections onto the STN and STN neurons make excitatory connections onto the GPe. Neurons within the GPe also make inhibitory connections with other GPe neurons and with the output neurons of the basal ganglia. The output nuclei of the basal ganglia consist of the internal segment of the globus pallidus (GPi) and the substantia nigra pars reticulata (SNr). Most inputs to the GPe arise from the striatum and are GABAergic. The GPe also receives excitatory inputs from the cerebral cortex and the intralaminar nuclei of the thalamus (Wilson 2010).

STN neurons also make excitatory connections with the output neurons. In addition to inhibitory input from GPe, the STN receives excitatory input from the frontal cortex, from the intralaminar thalamic nuclei, and from the pedunculopontine nucleus (Wilson 2010).

The STN and GPe are made up of repeating neuronal architectures so that functionally related regions of the STN and GPe are reciprocally connected and innervate functionally related regions of the basal ganglia output nuclei. Furthermore, the majority of STN and GPe neurons in rats and monkeys have branched axons that mediate both the reciprocal connections and the innervation of the basal ganglia output nuclei (Bevan et al. 2002).

The principal source of afferent input to the basal ganglia, the cerebral cortex, influences the STN–GPe network, directly via monosynaptic projections or indirectly via GABAergic striatal or glutamatergic thalamic neurons. Neuronal projections from the striatum to the output nuclei through the STN–GPe network are often referred to collectively as the *indirect pathway*. By virtue of their extensive innervation of the GABAergic neurons of the basal ganglia output nuclei, the STN and GPe are in a position to influence powerfully the communication of the basal ganglia with the rest of the brain (Bevan et al. 2002).

Origins of Rhythmic Activity in the STN–GPe Network

There has been considerable debate on the origins of correlated, rhythmic firing in the STN–GPe network. This activity could be an emergent property of the STN–GPe network itself and/or be driven by rhythmic activity outside the STN–GPe network.

Computational Modeling of STN–GPe Network Activity

Computational modeling studies incorporating the known biophysical properties of STN and GPe neurons, using a range of network architectures within the limits of the known anatomy, have been useful in examining the principles that underlie activity patterns in the STN–GPe network. Computer simulations in (Terman et al. 2002), for example, suggest that the STN–GPe network is capable of generating patterned and persistent activity of a variety of types; these include uncorrelated spiking activity, as arises during normal resting conditions, and synchronous bursting activity associated with pathological, Parkinsonian conditions. Rhythmic activity arises in the model through mutually coupled, excitatory–inhibitory interactions between the STN and GPe neurons: Synchronous bursting of GPe neurons generates sufficient hyperpolarization in STN neurons for rebound burst activity, which, in turn, drives bursting activity in GPe neurons and leads to continuation of the rhythm.

Recent studies have examined the role of structures, such as the striatum and cortex, outside the STN–GPe network in generating beta band and other oscillations (Bevan et al. 2002; Rubin et al. 2012). Moreover, the STN–GPe network model has been extended to include other neurons including those within the GPi, the thalamus, and the cortex. These studies have led to new hypotheses concerning mechanisms underlying the therapeutic effects of deep brain stimulation (Guo et al. 2008; Hahn and McIntyre 2010).

Subthreshold antiphase: Membrane potential antiphase; Subthreshold antiresonance: Membrane potential (amplitude) antiresonance; Subthreshold or membrane potential antiphase resonance

Definitions

Subthreshold (or membrane potential) antiresonance refers to the ability of neurons to exhibit a minimum in their voltage amplitude response to oscillatory input currents at a nonzero input (antiresonant) frequency.

Subthreshold (or membrane potential) antiphasonance refers to the ability of neurons to exhibit a zero-phase (or zero-phase-shift) response to oscillatory inputs currents at a non-zero (antiphasonant) frequency separating between delayed and advance responses for frequencies smaller and larger than the antiphasonant frequency, respectively.

Linear subthreshold antiresonance and antiphasonance refers to the occurrence of these phenomena in linear systems.

In this article, we focus on the description of antiresonance and antiphasonance in 3D linearized conductance-based models. Antiresonance and antiphasonance occur in 3D linear systems, but not in 2D ones. 3D linear systems may also exhibit resonance/phasonance without antiresonance/antiphasonance. We refer the reader to the companion article (Rotstein, chapter ► “[Subthreshold Resonance and Phasonance in Single Neurons: 2D Models](#)”) for further details and discussion on resonance and phasonance in 2D systems.

Detailed Description

Introduction

Subthreshold antiresonance has been observed in hippocampal CA1 pyramidal cells (Pike et al. 2000) and other cell types (Fox et al. 2016), and it has been studied theoretically by Richardson et al. (2003) and Rotstein (2017a). To our knowledge, subthreshold antiphasonance has not been experimentally reported in neuronal systems. However, the theoretical studies discussed here and in the references above suggest it should be present in some neurons exhibiting antiresonance.

Conductance-Based Models

In this article, we discuss the subthreshold resonant properties of neurons in the context of biophysical

(conductance-based) models (Skinner 2006; Hodgkin and Huxley 1952) whose subthreshold dynamics are governed by the following equations

$$C \frac{dV}{dt} = -I_L - \sum_{j=1}^3 I_j + I_{app} + I_{in}(t), \quad (1)$$

$$\frac{dx_j}{dt} = \frac{x_{j,\infty}(V) - x_j}{\tau_{j,x}(V)}, \quad j = 1, 2. \quad (2)$$

In the current-balance Eq. 1, V is the membrane potential (mV), t is time (msec), C is the membrane capacitance ($\mu\text{F}/\text{cm}^2$), I_{app} is the applied bias (DC) current ($\mu\text{A}/\text{cm}^2$), $I_L = G_L(V - E_L)$ is the leak current, and $I_j = G_j x_j(V - E_j)$ are generic expressions for ionic currents (with j an index) with maximal conductance G_j (mS/cm^2) and reversal potentials E_j (mV), respectively. The dynamics of the gating variables x_j are governed by the kinetic equations (2) where $x_{j,\infty}(V)$ and $\tau_{j,x}(V)$ are the voltage-dependent activation/inactivation curves and time constants, respectively. The generic ionic currents I_j we consider here are restricted to have a single gating variable x_j and to be linear in x_j . The persistent sodium, h-(hyperpolarization-activated, mixed-cation, inward), and slow-potassium (M-type) currents found to be responsible for the generation of subthreshold resonance in neurons of the hippocampus and the entorhinal cortex have this form (Schreiber et al. 2004; Hu et al. 2002, 2009; Pike et al. 2000; Rotstein et al. 2006; Izhikevich 2006). We focus on three-dimensional models describing the dynamics of V and two gating variables (x_1 and x_2). Additional currents whose gating variables evolve on a fast time, almost instantaneous timescale can be included by using the adiabatic approximation $x_j = x_{j,\infty}(V)$. Here we include one such fast current ($I_3 = G_3 x_{3,\infty}(V) (V - E_3)$). Additional fast currents can be included without significantly changing the formalism used here.

The function $I_{in}(t)$ in Eq. 1 is an oscillatory input current ($\mu\text{A}/\text{cm}^2$) of the form

$$I_{in}(t) = A_{in} \sin(\Omega t) \quad \text{with} \quad \Omega = \frac{2\pi f}{1000}, \quad (3)$$

where f is the input frequency (Hz).

Our discussion of subthreshold resonance can be easily adapted to ionic currents having two gating variables raised to powers not necessarily equal to one such as calcium currents (Hutcheon and Yarom 2000).

Linearized Conductance-Based Models

Linearization of the autonomous part ($I_{in}(t) = 0$) of system (1)–(2) around the fixed-point $(\bar{V}, \bar{x}_1, \bar{x}_2)$ yields (Richardson et al. 2003)

$$C \frac{dv}{dt} = -g_L v - g_1 w_1 - g_2 w_2 + I_{in}(t), \quad (4)$$

$$\tau_1 \frac{dw_1}{dt} = v - w_1, \quad (5)$$

$$\tau_2 \frac{dw_2}{dt} = v - w_2, \quad (6)$$

where

$$v = V - \bar{V}, \quad (7)$$

$$w_1 = \frac{x_1 - \bar{x}_1}{x'_{1,\infty}(\bar{V})}, \quad w_2 = \frac{x_2 - \bar{x}_2}{x'_{2,\infty}(\bar{V})},$$

$$\bar{x}_j = x_{j,\infty}(\bar{V}), \quad \tau_j = \tau_{x,j}(\bar{V}) \quad j = 1, 2, \quad (8)$$

$$g_j = G_j x'_{k,\infty}(\bar{V}) (\bar{V} - E_j), \quad j = 1, 2, 3, \quad (9)$$

and

$$g_L = G_L + G_1 x_{1,\infty}(\bar{V}) + G_2 x_{2,\infty}(\bar{V}) + G_3 x_{3,\infty}(\bar{V}) + g_3. \quad (10)$$

In Eqs. 7 and 9 $x'_{j,\infty} = dx_{j,\infty}/dV$ ($j = 1, 2, 3$). Note that the gating variables w_1 and w_2 in Eq. 7 have units of voltage ($[v] = [w_1] = [w_2] = \text{mV}$).

The signs of the effective ionic conductances g_j determine whether the associated gating variables are either resonant ($g_j > 0$) or amplifying ($g_j < 0$) (Richardson et al. 2003; Hutcheon and Yarom 2000). The effective leak conductance g_L Eq. 10 contains information about the biophysical leak conductance G_L , the ionic conductances, and their associated voltage-dependent

activation/inactivation curves. The fast ionic current I_3 contributes to g_L with an additional term (g_3). All terms in g_L are positive except for the last one that can be either positive or negative. Specifically, g_L can become negative for negative enough values of g_3 .

System (4)–(6) can be rescaled by defining the following dimensionless time and parameters

$$\hat{t} = \frac{t}{\tau_1}, \quad \gamma_L = \frac{g_L \tau_1}{C}, \quad \gamma_1 = \frac{g_1 \tau_1}{C}, \quad (11)$$

$$\gamma_2 = \frac{g_2 \tau_1}{C}, \quad \eta = \frac{\tau_1}{\tau_2}.$$

Substitution of Eq. 11 into Eqs. 4–6 and a further rearrangement of terms yields

$$\frac{dv}{d\hat{t}} = -\gamma_L v - \gamma_1 w_1 - \gamma_2 w_2 + \hat{I}_{in}(t), \quad (12)$$

$$\frac{dw_1}{d\hat{t}} = v - w_1, \quad (13)$$

$$\frac{dw_2}{d\hat{t}} = \eta[v - w_2]. \quad (14)$$

where γ_L , γ_1 and γ_2 are the dimensionless effective conductances and

$$\hat{I}_{in}(t) = \hat{A}_{in} \sin(2\pi f \tau_1 \hat{t}/1000) \text{ with } \hat{A}_{in} = \frac{A_{in} \tau_1}{C}. \quad (15)$$

Voltage Response: Impedance Amplitude and Phase

The voltage response of a neuron receiving an oscillatory input current is typically measured in terms of the so-called impedance function $\mathbf{Z}(f)$. $\mathbf{Z}(f)$ is a complex quantity with amplitude $|\mathbf{Z}(f)|$ and phase $\Phi(f)$. For simplicity, we refer to $|\mathbf{Z}(f)|$ simply as the impedance $Z(f)$.

For a linear system receiving a sinusoidal input current $I_{in}(t)$ of the form (3), the voltage response is given by

$$V_{out}(t, f) = A_{out}(f) \sin(\Omega t - \Phi(f)) \quad (16)$$

where $A_{out}(f)$ is the amplitude and $\Phi(f)$ is the difference between the peaks of $I_{in}(t)$ and $V_{out}(t; f)$. The impedance amplitude is given by

$$Z(f) = \frac{A_{out}(f)}{A_{in}}. \quad (17)$$

We refer the reader to the companion article (Rotstein, chapter ► [“Subthreshold Resonance and Phasance in Single Neurons: 2D Models”](#)) for additional details.

Impedance and Phase Profiles for Linear Systems

Impedance and phase profiles refer to the curves of the impedance and phase, respectively, as a function of the input frequency. For linear systems, the impedance and phase can be computed analytically (Rotstein 2017a) (see also textbooks such as (Boyce and DiPrima 2009) for additional techniques to solve ordinary differential equations).

We use here the following generic forced system

$$\begin{cases} X' = aX + bY + cZ + A_{in} e^{i\Omega t}, \\ Y' = \alpha X + pY, \\ Z' = \beta X + qZ, \end{cases}. \quad (18)$$

for constant $a, b, c, \alpha, \beta, p$ and q .

The characteristic polynomial for the corresponding homogeneous system ($A_{in} = 0$) is given by

$$\begin{aligned} & r^3 - (a + p + q) r^2 \\ & + (ap + aq + pq - c\beta - b\alpha)r + b\alpha q \\ & + c\beta p - apq = 0. \end{aligned} \quad (19)$$

The occurrence and properties of intrinsic subthreshold oscillations in 3D linear and linearized conductance-based models has been investigated by Rotstein (2017b).

Analytic Expressions

The particular solution to system (18) has the form

$$\begin{aligned} X_p(t) &= A_{out} e^{i\Omega t}, \\ Y_p(t) &= B_{out} e^{i\Omega t} \\ \text{and} \\ Z_p(t) &= C_{out} e^{i\Omega t}, \end{aligned} \quad (20)$$

Substituting Eq. 20 into system (18), rearranging terms, and solving the resulting algebraic system one obtains

$$\mathbf{Z}(\Omega) = \frac{A_{out}}{A_{in}} = \frac{P_r(\Omega) + iP_i(\Omega)}{Q_r(\Omega) + iQ_i(\Omega)} \quad (21)$$

where

$$P_r(\Omega) = pq - \Omega^2, \quad (22)$$

$$P_i(\Omega) = -(p + q)\Omega, \quad (23)$$

$$\begin{aligned} Q_r(\Omega) &= (a + p + q)\Omega^2 - apq + b\alpha q \\ &+ c\beta p, \end{aligned} \quad (24)$$

and

$$Q_i(\Omega) = (ap + aq + pq - b\alpha - c\beta - \Omega^2)\Omega. \quad (25)$$

From Eq. 21

$$Z(\Omega) := \frac{A_{out}}{A_{in}} = \sqrt{\frac{P_r^2(\Omega) + P_i^2(\Omega)}{Q_r^2(\Omega) + Q_i^2(\Omega)}} \quad (26)$$

and

$$\Phi = \tan^{-1} \frac{P_r(\Omega)Q_i(\Omega) - P_i(\Omega)Q_r(\Omega)}{P_r(\Omega)Q_r(\Omega) + P_i(\Omega)Q_i(\Omega)}. \quad (27)$$

For a 2D linear system ($c = q = 0$), the characteristic polynomial for the corresponding homogeneous system ($A_{in} = 0$) and the impedance and phase profiles reduce to those presented in the companion article (Rotstein, chapter ► [“Subthreshold Resonance and Phasance in Single Neurons: 2D Models”](#)) with c and d substituted by α and p .

Antiresonance and Antiphase

In certain parameter regimes (discussed later in this article), the voltage response for 3D linear systems is more complex than for 2D linear ones (Richardson et al. 2003; Pike et al. 2000; Rotstein 2017a) (see also the companion article (Rotstein, chapter ► “Subthreshold Resonance and Phasance in Single Neurons: 2D Models”). In addition to resonance (impedance profile peak Z_{max} at $f = f_{res}$, Fig. 2-C5) and phasance (zero-phase response with positive

slope at $f = f_{phas}$, Fig. 2-C4), 3D linear models can exhibit antiresonance and antiphase when the impedance profile exhibits a trough Z_{min} at an (antiresonant) input frequency $f = f_{ares}$ (Figs. 1-A1 and 2-C2) and the phase profile has an additional zero-frequency cross at $f = f_{aphas}$ (Figs. 1-A2 and 2-C3) in addition to the one at $f = f_{phas}$. Note that the slope of Φ at f_{aphas} is negative (opposite to the slope of Φ at f_{phas}). For $f = f_{aphas}$ and $f = f_{phas}$, the input current and output voltage peak at the same time (Fig. 2-C3

Subthreshold Antiresonance and Antiphase in Single Neurons: 3D Models, Fig. 1 Schematic diagrams of the impedance (left) and phase (right) profiles for a 3D system (A) and a 2D system (B). The impedance (Z) and phase (Φ) profiles are the curves of Z and Φ as a function of the input frequency f . **A.** The 3D system exhibits antiresonance (A1) and antiphase (A2) in addition to resonance (A1) and phasance (A2). The impedance profile Z is characterized by seven attributes: the resonant frequency f_{res} , the antiresonant frequency f_{ares} ,

the impedance peak Z_{max} , the impedance local minimum Z_{min} , the resonance amplitude $Q_Z = Z_{max} - Z_{min}$, and $Q_0 = Z_{max} = Z_0$ and the half-bandwidth $\Lambda_{1/2}$. The phase profile Φ is characterized by two attributes: the phasant frequency f_{phas} , the antiphase frequency f_{aphas} , the phase minimum Φ_{min} , the phase maximum Φ_{max} . **B.** For a system exhibiting resonance without antiresonance (B1), $Z_{min} = Z_0$ and therefore $Q_Z = Q_0$. For a system exhibiting phasance without antiphase (B2), $\Phi_{max} = 0$

Subthreshold Antiresonance and Antiphase in Single Neurons: 3D Models, Fig. 2 (continued)

and -C4). The voltage response is delayed for $f < f_{phas}$ (Fig. 2-C1) and $f > f_{phas}$ (Fig. 2-C5 and -C6) and advanced for f satisfying $f_{phas} < f < f_{aphas}$ (not shown).

Attributes of the Impedance and Phase Profiles

As for the 2D systems discussed in Rotstein (chapter ▶ “Subthreshold Resonance and Phasonance in Single Neurons: 2D Models”), the tracking of the changes in the impedance and phase profiles as the model parameters change is simplified by using a small number of attributes that capture the salient properties of these curves. For systems exhibiting resonance and antiresonance (Fig. 1-A1), the impedance profile Z is characterized by seven attributes: the resonant frequency f_{res} , the antiresonant frequency f_{ares} , the impedance peak Z_{max} , the impedance local minimum Z_{min} , the resonance amplitude $Q_Z = Z_{max} - Z_{min}$, and $Q_0 = Z_{max} - Z_0$ and the half-bandwidth $\Lambda_{1/2}$. For a system exhibiting resonance without antiresonance (Fig. 1-B1), $Z_{min} = Z_0$ and therefore $Q_Z = Q_0$. For systems exhibiting phasonance and antiphasonance (Fig. 1-A2), the phase profile Φ is characterized by two attributes: the phasant frequency f_{phas} , the antiphasant frequency f_{aphas} , the phase minimum Φ_{min} , the phase maximum ϕ_{max} . For a system exhibiting phasonance without antiphasonance (Fig. 1-B2) $\Phi_{max} = 0$.

Mechanisms of Generation of Antiresonance and Antiphasonance

Antiresonance and antiphasonance emerge as the result of the interplay of a slow resonant gating variable ($g_1 > 0$) and a slower amplifying gating variable ($g_2 < 0$) in systems that exhibit resonance

for $g_2 = 0$. Alternatively, the generation of antiresonance requires $\gamma_2 < 0$ and $\eta < 1$ in the rescaled system (12)–(14). This is illustrated in Fig. 3 for a baseline system ($g_2 = 0$) that exhibits both resonance and phasonance (blue curves in all panels). Each panel shows the effects of decreasing values of $g_2 < 0$ for various representative values of τ_2 that is above (panels A and B), equal to (panel C) and below (panel D) the value of τ_1 .

For $\tau_2 = 0.1$ (Fig. 3-A) decreasing values of g_2 cause a strong amplification of the voltage response and a slight decrease in f_{res} and f_{phas} as expected from the effects of amplifying linearized conductances in quasi-2D systems. For larger values of τ_2 , but still $\tau_2 < \tau_1$, the amplification of the voltage response persists, but is less pronounced as τ_2 increases (Fig. 3-B). The changes in f_{res} and f_{phas} are more pronounced as τ_2 increases.

Figure 3-C illustrates the annihilation of resonance and phasonance for $\tau_2 = \tau_1$. In these cases, the 3D system is quasi-2D since after the transients have disappeared $w_2 = w_1$. The opposite signs of the two linearized conductances can cause the system to exhibit resonance or not depending on the net sign of the sum of the two conductances.

Antiresonance and antiphasonance emerge when τ_2 increases above τ_1 (Fig. 3-D). This can be better understood by looking at system (12)–(14) for the limiting case $n \rightarrow 0$. A rescaling of time $f t \rightarrow t$ moves the input frequency f from the sinusoidal input to the denominator of the right hand-side of the three equations. If $f > \eta$ ($n/f \rightarrow 0$), w_2 has no dynamics. The 3D systems behave as the 2D system for $g_2 = 0$ with a resistance given by $Z(0) = (g_L + g_1)^{-1}$. As f decreases with $n < f < f_{res}$, the impedance profile decreases to this value. This 2D reduction is no longer valid when $f < \eta$. Therefore, $Z(0) = (g_L + g_1 + g_2)^{-1}$. As

Subthreshold Antiresonance and Antiphasonance in Single Neurons: 3D Models, Fig. 2 Resonance and phasonance for the linear system (4)–(6) for representative parameter values. **A.** Impedance profile. **B.** Phase profile. **C.** Voltage responses (solid-blue) to sinusoidal input currents I_{in} (dashed-red) for representative input frequencies f (black dots in the impedance and phase profiles). Only one period is shown for each value of f . The input is superimposed to the graph for clarity. The vertical dashed-

red lines indicate the input peak. The horizontal dashed-black lines correspond to Z_{max} (in the impedance profile), which is reached by the voltage response only when $f = f_{res}$. The blue dots indicate the peak of the voltage response. **C1.** Phase delay. **C2.** Antiresonance and phase delay. **C3.** Antiphasonance. **C4.** Phasonance. **C5.** Resonance and phase delay. **C6.** Phase delay. We used the following parameter values: $C = 1$, $g_L = 0.1$, $g_1 = 0.305$, $g_2 = -0.25$, $\tau_1 = 10$, $\tau_2 = 150$ and $A_{in} = 1$

Subthreshold Antiresonance and Antiphase in Single Neurons: 3D Models, Fig. 3 Impedance and phase profiles for system (4)–(6) with $g_2 < 0$ (interaction between a negative and a positive feedback effects) for

representative sets of parameter values. The gray lines in the left panels connect the peaks of the impedance profiles. We used the following parameter values $C = 1$, $g_L = 0.25$, $g_1 = 0.25$, $\tau_1 = 100$, and $A_{in} = 1$

$f \rightarrow 0$, the dynamics is quasi-1D and the impedance increases to this value $Z(0)$ (a decreasing function of g_2). The generation of antiresonance is the only way in which the impedance can satisfy these two opposite behaviors as f changes without losing continuity. Under certain conditions, it occurs in an asymptotic boundary layer in the frequency domain (Rotstein 2017a).

Synonyms

Subthreshold resonance: Membrane potential (amplitude) resonance

Subthreshold phasance: Membrane potential phasance, subthreshold or membrane potential phase resonance

Definitions

Subthreshold (or membrane potential) resonance refers to the ability of neurons to exhibit a peak in their voltage amplitude response to oscillatory input currents at a preferred (resonant) frequency.

Subthreshold (or membrane potential) phasance refers to the ability of neurons to exhibit a zero-phase (or zero-phase-shift) response to oscillatory inputs currents at a nonzero (phasant) frequency separating between advanced and delayed responses for frequencies smaller and larger than the phasant frequency, respectively.

Linear subthreshold resonance and phasance refers to the occurrence of these phenomena in linear systems.

Nonlinear subthreshold resonance and phasance refers to the occurrence of these phenomena in nonlinear systems where at least one of the linearity principles is not satisfied.

In this article we focus on 2D linearized conductance-based models and 2D conductance-based models with parabolic- and cubic-like nonlinearities in the voltage equation for which (i) the input and output frequencies coincide and (ii) the amplitude of the steady state voltage response is uniform across cycles for each input frequency. In the companion article (Rotstein 2017a) we discuss the related phenomena of antiresonance and anti-phasance in 3D linear models, which cannot be exhibited by the 2D models discussed here.

Detailed Description

Introduction

Subthreshold resonance has been observed in various neuron types in the hippocampus and the entorhinal cortex (Hutcheon and Yarom 2000; Pike et al. 2000; Schreiber et al. 2004; Zemankovics et al. 2010; Hu et al. 2002, 2009; Leung and Yu 1998; Erchova et al. 2004; Heyes et al. 2010; Engel et al. 2008; Wang et al. 2006) as

well as in other neural systems (Hutcheon et al. 1996a, 1994; Art et al. 1986; Tohidi and Nadim 2009; Tseng and Nadim 2010; Castro-Alamancos et al. 2007; Wu et al. 2001; Gastrein et al. 2011; Sciamanna and Wilson 2011; Mikiel-Hunter et al. 2016; D'angelo et al. 2001; Ulrich 2002). The functionality of the resonant properties of neurons has not been established yet. However, resonance in single cells (e.g., hippocampal principal cells, medial entorhinal cortex layer II stellate cells, and hippocampal interneurons) has been implicated in the generation of rhythmic activity in the networks in which they are embedded in frequency bands that coincide with the resonant frequency of these neurons (Tikidji-Hamburyan et al. 2015; Tchumatchenko and Clopath 2014; Moca et al. 2014) (but see (Stark et al. 2013)).

Theoretical studies on neuronal resonance have been performed using linear models (either caricature models or linearization of conductance-based models), which are analytically solvable, or nonlinear conductance-based models, by using direct simulations or dynamical systems tools (Richardson et al. 2003; Gutfreund et al. 1995; Schreiber et al. 2004; Haas and White 2002; Alexander et al. 1990; Izhikevich 2001, 2002; Hutcheon et al. 1994, 1996b; Reinker et al. 2004; Rotstein and Nadim 2014; Rotstein 2014, 2015, 2017b).

Conductance-Based Models

We discuss the subthreshold resonant properties of neurons in the context of biophysical (conductance-based) models (Skinner 2006; Hodgkin and Huxley 1952) whose subthreshold dynamics are governed by the following equations

$$C \frac{dV}{dt} = -I_L - I_1 - I_2 + I_{app} + I_{in}(t), \quad (1)$$

$$\frac{dx_1}{dt} = \frac{x_{1,\infty}(V) - x_1}{\tau_{1,x}(V)}, \quad (2)$$

In the current-balance equation (1), V is the membrane potential (mV), t is time (msec), C is the membrane capacitance ($\mu\text{F}/\text{cm}^2$), I_{app} is the applied bias (DC) current ($\mu\text{A}/\text{cm}^2$), $I_L = G_L (V - E_L)$ is the

leak current, and $I_j = G_j x_j (V - E_j)$ are generic expressions for ionic currents ($j = 1, 2$) with maximal conductance G_j (mS/cm²) and reversal potentials E_j (mV), respectively. The dynamics of the gating variables x_j are governed by the kinetic equations (2) where $x_{j,\infty}(V)$ and $\tau_{j,\infty}(V)$ are the voltage-dependent activation/inactivation curves and time constants, respectively.

The generic ionic currents I_j we consider here are restricted to have a single gating variable x_j and to be linear in x_j . Various currents that have been found to be involved in the generation of subthreshold resonance in neurons of the hippocampus and the entorhinal cortex have this form (Schreiber et al. 2004; Hu et al. 2002, 2009; Pike et al. 2000; Rotstein et al. 2006; Izhikevich 2006). Examples include the persistent sodium (I_{Nap}), hyperpolarization-activated, mixed-cation, inward or h- (I_h), slow-potassium, M-type (I_{Ks}), and inward-rectifying potassium (I_{Kir}) currents.

We focus on two-dimensional models describing the dynamics of V and a gating variable (x_1). Additional currents whose gating variables evolve on a very fast, almost instantaneous time scale can be included by using the adiabatic approximation. Here we include one such fast current: $I_2 = G_2 x_{2,\infty}(V) (V - E_2)$ where $x_2 = x_{2,\infty}(V)$. Additional fast currents can be included without significantly changing the formalism used here.

The function $I_{in}(t)$ in Eq. 1 is an oscillatory input current ($\mu\text{A}/\text{cm}^2$) of the form

$$I_{in}(t) = A_{in} \sin(\Omega t) \text{ with } \Omega = \frac{2\pi f}{1000}, \quad (3)$$

where f is the input frequency (Hz).

Our discussion of subthreshold resonance can be easily adapted to ionic currents having two gating variables raised to powers not necessarily equal to one such as calcium currents (Hutcheon and Yarom 2000).

Linearized Conductance-Based Models

Linearization of the autonomous part of system Eqs. 1 and 2 around the fixed-point $(\bar{V}, \bar{x}_1)$ yields (Richardson et al. 2003)

$$C \frac{dv}{dt} = -g_L v - g_1 w_1 + I_{in}(t), \quad (4)$$

$$\tau_1 \frac{dw_1}{dt} = v - w_1, \quad (5)$$

where

$$v = V - \bar{V}, \quad w_1 = \frac{x_1 - \bar{x}_1}{x'_{1,\infty}(\bar{V})}, \quad (6)$$

$$\bar{x}_1 = x_{1,\infty}(\bar{V}), \quad \tau_1 = \tau_{x,1}(\bar{V}) \quad (7)$$

$$g_j = G_j x'_{j,\infty}(\bar{V}) (\bar{V} - E_j), \quad j = 1, 2, \quad (8)$$

and

$$g_L = G_L + G_1 x_{1,\infty}(\bar{V}) + G_2 x_{2,\infty}(\bar{V}) + g_2. \quad (9)$$

In Eqs. 6 and 8 $x'_{j,\infty} = dx_{j,\infty}/dV$ ($j = 1, 2$). Note that the gating variable w_1 in Eq. 6 has units of voltage ($[v] = [w_1] = \text{mV}$).

The effective leak conductance g_L Eq. 9 contains information about the biophysical leak conductance G_L , the ionic conductances, and their associated voltage-dependent activation/inactivation curves. The fast ionic current I_2 contributes to g_L with an additional term (g_2). All terms in g_L are positive except for the last one that can be either positive or negative. Specifically, g_L can become negative for negative enough values of g_2 .

System Eqs. 4 and 5 can be rescaled by defining the following dimensionless time and parameters

$$\hat{t} = \frac{t}{\tau_1}, \quad \gamma_L = \frac{g_L \tau_1}{C}, \quad \gamma_1 = \frac{g_1 \tau_1}{C}. \quad (10)$$

Substitution of Eq. 10 into Eqs. 4 and 5 and a further rearrangement of terms yields

$$\frac{dv}{d\hat{t}} = -\gamma_L v - \gamma_1 w_1 + \hat{I}_{in}(t), \quad (11)$$

$$\frac{dw_1}{d\hat{t}} = v - w_1, \quad (12)$$

where γ_L, γ_1 are the dimensionless effective conductances and

$$\hat{I}_{in}(t) = \hat{A}_{in} \sin(2\pi f \tau_1 \hat{t}/1000) \quad \text{with} \quad = \frac{A_{in} \tau_1}{C}. \quad Z(f) = \frac{A_{out}(f)}{A_{in}}. \quad (15)$$

Conductance-Based Models with Subthreshold Parabolic- and Cubic-like Nonlinearities

In this paper we discuss two models that have the same type of ionic currents, I_h and I_{Nap} , but different parameter values that endow them with different geometric and dynamic properties reflected in the shapes of the voltage V -nullclines in the phase-plane diagram (Rotstein 2017b): parabolic- and cubic-like. $I_{Nap} = G_p p_\infty(V)$ ($V - E_{Na}$) has a fast amplifying gating variable (slave to voltage) and $I_h = G_h r(V - E_h)$ has a slower resonant gating variable. We refer to these models as the parabolic- and cubic-like $I_h + I_{Nap}$ models (Fig. 1-A and -B, respectively). Both models are able to produce subthreshold oscillations (STOs) in the presence of noise (Fig. 1). In the absence of noise, the parabolic-like model produces at most damped STOs, but not limit cycle STOs (Touboul 2008), while the cubic-like model admits limit cycle STOs when the fixed-point is an unstable foci (Rotstein 2017c; White et al. 1995). Other models have the same types of dual nonlinearities and dynamic properties. For example, the $I_{Nap} + I_{Ks}$ model (Rotstein 2017b).

Voltage Response: Impedance Amplitude and Phase

The voltage response of a neuron receiving an oscillatory input current is typically measured in terms of the so-called impedance function $\mathbf{Z}(f)$. $\mathbf{Z}(f)$ is a complex quantity with amplitude $|\mathbf{Z}(f)|$ and phase $\Phi(f)$. For simplicity, we refer to $|\mathbf{Z}(f)|$ simply as the impedance $Z(f)$.

For a linear system receiving a sinusoidal input current $I_{in}(t)$ of the form Eq. 3, the voltage response is given by

$$V_{out}(t, f) = A_{out}(f) \sin(\Omega t - \Phi(f)) \quad (14)$$

where $A_{out}(f)$ is the amplitude and $\Phi(f)$ is the difference between the peaks of $I_{in}(t)$ and $V_{out}(t, f)$. The impedance amplitude is given by

For nonlinear systems, or for linear systems with nonsinusoidal inputs, Eq. 15 does no longer provide an appropriate definition of the impedance function. Assuming the input and output frequencies coincide and the output amplitude is uniform across cycles for a given input (with constant amplitude), the definition of the impedance amplitude can be extended to

$$Z(f) = \frac{V_{max}(f) - V_{min}(f)}{2A_{in}} \quad (16)$$

where $V_{max}(f)$ and $V_{min}(f)$ are the maximum and minimum of the oscillatory voltage response $V_{out}(t, f)$ for each value of the input frequency f . For linear systems receiving sinusoidal inputs, Eqs. 16 and 15 are equivalent. Similarly to the linear case $\Phi(f)$, the phase is computed as the distance between the peaks of the output and the input (within the same input cycle) normalized by the period.

For more general systems and inputs the impedance has been computed as the quotient between the Fourier transforms of the output voltage $V_{out}(t, f)$ and the input current $I_{in}(t)$

$$\mathbf{Z}(f) = \left| \frac{\mathcal{F}[V_{out}(t, f)](f)}{\mathcal{F}[I_{in}(t)](f)} \right|. \quad (17)$$

For linear systems (15) is equivalent to (17).

Several authors have used the so-called ZAP current (Puil et al. 1986; Hutcheon and Yarom 2000)

$$I_{in}(t) = I_{Zap}(t) = A_{in} \sin(2\pi f(t)t), \quad f(t) = \frac{f_M t}{2T_M}, \quad (18)$$

that sweeps through a given range of frequencies over time with a maximum frequency f_M and a stimulus length T_M (Other types of time-dependent input frequencies have also been used (Tseng and Nadim 2010)). The corresponding impedance function can be computed using 17. Note that Eq. 16 can be thought of as a filtered

Subthreshold Resonance and Phasonance in Single Neurons: 2D Models, Fig. 1 Subthreshold oscillations (STOs) and phase-plane diagrams for the autonomous parabolic-like (A) and cubic-like (B) $I_h + I_{Nap}$ models for representative parameter values. The STOs have been created using white noise. In the absence of noise both models have a stable fixed-point (focus). For visualization purposes, only one STO cycle is shown in the phase-plane diagrams (A1 and B1, left). **A. Parabolic-like $I_h + I_{Nap}$ model.** We used the following parameter values and functions: $C = 1$, $G_L = 0.5$,

$G_p = 0.5$, $G_h = 1.5$, $E_L = -65$, $E_{Na} = 55$, $E_h = -20$, $I_{app} = -2.25$, $\tau_r = 80$, $p_\infty(V) = (1 + e^{-(V+38)/6.5})^{-1}$, and $r_\infty(V) = (1 + e^{(V+79)/10})^{-1}$. The model is adapted from Rotstein et al. (2006) and Rotstein (2017d). **B. Cubic-like $I_h + I_{Nap}$ model.** We used the following parameter values and functions: $C = 1$, $G_L = 0.3$, $G_p = 0.08$, $G_h = 1.5$, $E_L = -75$, $E_{Na} = 42$, $E_h = -26$, $I_{app} = 0.4$, $\tau_r = 80$, $p_\infty(V) = (1 + e^{-(V+54.8)/4.4})^{-1}$, and $r_\infty(V) = (1 + e^{(V+74.2)/7.2})^{-1}$. The model is adapted from Remme et al. (2012) and Rotstein (2017d).

version of the impedance function computed using the ZAP functions. ZAP currents are useful for some experimental purposes, but make strong assumptions about the underlying ionic process, particularly their time scales, and should be used with caution.

Impedance and Phase Profiles for 2D Linear Systems

Impedance and phase profiles refer to the curves of the impedance and phase, respectively, as a function of the input frequency. For linear systems, the impedance and phase can be computed

analytically (Rotstein 2014) (see also textbooks such as Boyce and DiPrima 2009 for additional techniques to solve ordinary differential equations).

We use the following generic forced system

$$\frac{dx}{dt} = ax + by + A_{in} \sin(\Omega t), \quad (19)$$

$$\frac{dy}{dt} = cx + dy, \quad (20)$$

for constant a, b, c , and d .

The roots of the characteristic polynomial for the corresponding homogeneous system ($A_{in} = 0$)

$$r^2 - (a + d)r + ad - bc = 0, \quad (21)$$

are given by

$$r_{1,2} = \frac{(a + d) \pm \sqrt{(a - d)^2 + 4bc}}{2}. \quad (22)$$

Impedance and Phase Profiles: Analytic Expressions

The unforced system displays oscillations for values of the parameters satisfying $4bc + (a - d)^2 < 0$ with the natural frequency given by

$$\Omega_{nat} = \frac{\sqrt{-4bc - (a - d)^2}}{2}. \quad (23)$$

The impedance and phase profiles are given by (Rotstein 2014)

$$Z(\Omega) = \sqrt{\frac{d^2 + \Omega^2}{[ad - bc - \Omega^2]^2 + (a + d)^2 \Omega^2}} \quad (24)$$

and

$$\Phi(\Omega) = \tan^{-1} \frac{(ad - bc - \Omega^2)\Omega - (a + d)\Omega d}{(ad - bc - \Omega^2)d + (a + d)\Omega^2}, \quad (25)$$

respectively, and the resonant frequency is given by

$$\Omega_{res} = \sqrt{-d^2 + \sqrt{b^2 c^2 - 2abcd - 2d^2 bc}}, \quad (26)$$

provided the quantities inside the radicals are both positive.

Impedance and Phase Profiles: Resonance and Phasance

For 2D linear systems the impedance profile is either a decreasing function of f (Fig. 2-A2) representing a low-pass filter response, or it exhibits a peak at a nonzero (resonant) input frequency f_{res} (Fig. 2-A1) representing a band-pass filter. The phase profile is either an increasing function of f converging asymptotically to $\Phi = \pi/2$ (Fig. 2-B2) representing a delayed response for all values of f , or it exhibits a zero-phase response at a nonzero (phasant) input frequency f_{phas} (Fig. 2-B1). For input frequencies $f = f_{phas}$ the input current and output voltage peak at the same time (Fig. 3-C2). For input frequencies $f < f_{phas}$, the voltage response is advanced (Fig. 3-C1), while for input frequencies $f > f_{phas}$ the voltage response is delayed (Fig. 3-C3 and -C4).

Phase advance and delay have also been observed in the so-called phase response curves (PRCs) (Winfree 2001; Kuramoto 1984; Canavier 2014) where one computes the transient response of a steady state oscillation to a small, brief, non-oscillatory perturbation.

Impedance and Phase Profiles: Attributes

In order to track the changes in the impedance and phase profiles as the model parameters change it is useful to identify a small number of attributes of these curves that capture their salient properties. For 2D linear systems the impedance profile can be characterized by four attributes (Fig. 2-A1): the resonant frequency f_{res} , the maximum impedance Z_{max} , the resonance amplitude $Q_Z = Z_{max} - Z(0)$, and the half-bandwidth $\Lambda_{1/2}$. Some authors define the resonance amplitude as $Q = Z_{max}/Z(0)$. For a low-pass filter response

Subthreshold Resonance and Phasonance in Single Neurons: 2D Models, Fig. 2 Schematic diagrams of the impedance (A) and phase (B) profiles. The impedance (Z) and phase (Φ) profiles are the curves of Z and Φ as a function of the input frequency f . The impedance Z is characterized by four attributes: the resonant frequency f_{res} , the impedance peak $Z_{\max}$, the resonance amplitude $Q_Z = Z_{\max} - Z(0)$, and the half-bandwidth $\Delta_{1/2}$. **A2**: The

phase Φ is characterized by two attributes: the zero-crossing frequency f_{phas} and the phase minimum $\Phi_{\min}$. **A1**. Resonance (band-pass filter). **A2**. Absence of resonance (low-pass filter). **B1**. Phasonance. The voltage response is advanced for $f < f_{\text{phas}}$ and delayed for $f > f_{\text{phas}}$. **B2**. Absence of phasonance. The voltage response is delayed for all values of f .

$Q_Z = 0$ ($Q = 1$). Resonance requires $Q_Z > 0$ ($Q > 1$). The phase profile can be characterized by two attributes (Fig. 2-B1): the phasont frequency f_{phas} and the minimum phase $\Phi_{\min}$. A phasont response requires $\Phi_{\min} < 0$.

Subthreshold Resonance, Phasonance, and Intrinsic Oscillations

Subthreshold resonance, phasonance, and intrinsic (damped) oscillations are different phenomena

generated by different, though related, mechanisms (Richardson et al. 2003; Rotstein and Nadim 2014; Rotstein 2014). This is illustrated in Fig. 4 for the rescaled linear system Eqs. 11 and 12. The values of the natural, resonant, and phasont frequencies for the linear system Eqs. 4 and 5 are given, respectively, by

$$\Omega_{\text{nat}} = \frac{1}{2\tau_1 C} \sqrt{4g_1\tau_1 C + (C - g_L\tau_1)^2}, \quad (27)$$

Subthreshold Resonance and Phasance in Single Neurons: 2D Models,

Fig. 3 Resonance and phasance for the linear system Eqs. 4 and 5 for representative parameter values. **A.** Impedance profile. **B.** Phase profile. **C.** Voltage responses (solid blue) to sinusoidal input currents I_{in} (dashed red) for representative input frequencies f (black dots in the impedance and phase profiles). Only one period is shown for each value of f . The input is superimposed to the graph for clarity. The vertical dashed red lines indicate the input peak. The horizontal dashed black lines correspond to Z_{max} (in the impedance profile), which is reached by the voltage response only when $f = f_{res}$. The blue dots indicate the peak of the voltage response. **C1.** Phase advance. **C2.** Phasance. **C3.** Resonance and phase delay. **C4.** Phase delay. We used the following parameter values: $C = 1$, $g_L = 0.25$, $g_1 = 0.22$, $\tau_1 = 100$, and $A_{in} = 1$

$$\Omega_{res} = \frac{1}{\tau_1} \times \sqrt{\sqrt{\frac{g_1^2 \tau_1^2 + 2g_L g_1 \tau_1^2 + 2g_1 \tau_1 C}{C^2}} - 1}, \quad (28)$$

and

$$\Omega_{phas} = \frac{1}{\tau_1} \sqrt{\frac{g_1 \tau_1 - C}{C}}. \quad (29)$$

Note that substituting $C = \tau_1 = 1$, $g_L = \gamma_L$, and $g_1 = \gamma_1$ in Eqs. 27 and 29 gives the natural, resonant and phasant frequencies for the rescaled linear system Eqs. 11 and 12.

The differences between these phenomena are also exemplified by the simpler so-called $\lambda - \omega$ system (Kopell and Howard 1973)

$$\frac{dx}{dt} = -\lambda x - \omega y, \quad (30)$$

$$\frac{dy}{dt} = \omega x - \lambda y, \quad (31)$$

with $\lambda > 0$ and $\omega > 0$, whose complex eigenvalues are given by

$$r_{1,2} = -\lambda \pm i\omega. \quad (32)$$

The natural, resonant, and phase-resonant frequencies, which are given by

Subthreshold Resonance and Phasonance in Single Neurons: 2D Models, Fig. 4 Stability and resonance diagrams for the reduced 2D linear system Eqs. 11 and 12 in the γ_L - γ_1 parameter space. **A.** Stability diagram. The blue curves separate between regions with different stability properties. **B.** Resonance diagram. The red curves separate between regions where the system does (above) and does not (below) exhibit resonance. **C.** Phase-resonance

diagram. The green line separates between regions where the system does (above) and does not (below) exhibit phase-resonance. **D.** Superimposed stability (blue curves), resonance (red curves), and phase-resonance (green line) diagrams showing that intrinsic oscillations and resonance may occur in the absence of the other and resonance may occur in the absence of phase-resonance. The right panel is a magnification of the left one

$$\Omega_{nat} = \omega \quad \Omega_{res} = \sqrt{-\lambda^2 + \omega \sqrt{4\lambda^2 + g\omega^2}} \quad \text{and} \quad \Omega_{phas} = \sqrt{\omega^2 - \lambda^2}, \quad (33)$$

only coincide for $\lambda = 0$ when the system is a harmonic oscillator.

Note that system Eqs. 30 and 31 can be transformed into a rescaled system of the form Eqs. 11 and 12 by defining

$$v = \omega x, \quad w = \lambda y, \quad \hat{t} = \lambda t \quad \gamma_L = 1 \quad \gamma_1 = \frac{\omega^2}{\lambda^2}. \quad (34)$$

Resonant and Amplifying Currents and Gating Variables

Subthreshold resonance results from a combination of low- and high-pass filter mechanisms that have

been described in terms of ionic currents (Hutcheon and Yarom 2000) and the interplay of the neuronal effective time scales and the time scales of the oscillatory inputs (Rotstein 2014, 2015).

Passive currents (in particular capacitive currents) act as low-pass filters (see Fig. 2-A2). The so-called resonant currents provide the slow negative feedback effects necessary to create a preferred frequency band. Amplifying currents, on the other hand, have been argued to generate a positive feedback effect that enhances voltage changes, and hence make existing resonances more pronounced (Hutcheon and Yarom 2000) but they are not able to create resonance by themselves in the absence of a resonant current. Amplifying currents also affect the resonant frequency and other attributes of the voltage response such as f_{res} and f_{phas} (Rotstein and Nadim 2014).

The signs of the effective ionic conductances g_j Eq. 8 determine whether the associated gating

variables are either resonant ($g_j > 0$) or amplifying ($g_j < 0$) (Richardson et al. 2003; Hutcheon and Yarom 2000). Restorative and regenerative currents having a single gating variable can be referred to as resonant and amplifying, respectively. The former include I_h (inward inactivating) and I_{Ks} (outward activating), while the latter include I_{Nap} (inward activating) and I_{Kir} (outward inactivating) (Haas and White 2002; Schreiber et al. 2004; Hutcheon et al. 1996a; Gutfreund et al. 1995; Richardson et al. 2003). Some ionic currents may have both resonant and amplifying gating variables (e.g., I_A , I_{CaT}) (Hutcheon and Yarom 2000).

Mechanisms of Generation of Subthreshold Resonance and Phasonance

The investigation of the biophysical mechanisms of generation of resonance and phasonance consists of tracking the changes in the impedance and phase profiles as certain model parameters of interest change while keeping the remaining parameters fixed. This task is greatly simplified if one uses the attributes of the impedance and phase profiles instead of the full graphs.

This mechanistic investigation can be performed at different modeling levels by looking at (i) the dimensionless effective parameters in the rescaled system Eqs. 11 and 12, (ii) the effective parameters in the linearized system Eqs. 4 and 5,

or (iii) the biophysical parameters in the original conductance-based model.

For the rescaled system Eqs. 11 and 12 heat graphs of the impedance and phase profiles attributes can be plotted in the γ_L - γ_1 parameter space presented in Fig. 4 (Rotstein and Nadim 2014). These graphs can be used to investigate the effects of changes in parameters at the different levels of description mentioned above including (i) the effects of changes in the dimensionless effective conductances γ_L and γ_1 , by moving in either horizontal (γ_L) and vertical (γ_1) directions, respectively; (ii) the effects of changes in the effective conductances g_L and g_1 , by moving in either horizontal (g_L) and vertical directions (g_1) using the rescaling Eq. 10 to account for the values of τ_1 and C ; (iii) the effects of changes in the time constant τ_1 , by moving along oblique lines (parametrized by τ_1) with slope g_1/g_L in the attribute graphs; and (iv) the effects of changes in the biophysical parameters of the original conductance-based model to the linear level of approximation, by using the formulas (8) and (9) for the effective ionic (g_1 and g_2) and leak (g_L) conductances in terms of the biophysical conductances (G_L , G_1 , and G_2), the resting potential, and other biophysical parameters. Changes in the biophysical conductances generate non-linear curves in the γ_L - γ_1 parameter space

$I_h + I_{Nap}$ model with parabolic-like nonlinearities in the subthreshold voltage regime. We used the same parameter values and functions as in Fig. 1-A

Subthreshold Resonance and Phasonance in Single Neurons: 2D Models, Fig. 6 Impedance (left columns), voltage envelope (middle columns), and phase (right columns) profiles for the sinusoidally forced

$I_h + I_{Nap}$ model with cubic-like nonlinearities in the subthreshold voltage regime. We used the same parameter values and functions as in Fig. 1-B

(Rotstein and Nadim 2014). These nonlinear curves reflect the different effects caused by different types of resonant and amplifying currents (Rotstein and Nadim 2014).

Nonlinear Resonance and Phasonance in Models with Subthreshold Parabolic- and Cubic-like Nonlinearities

The linear steady state responses to sinusoidal inputs satisfy three properties: (i) the input and output frequencies coincide, (ii) the output is proportional to the input for each input frequency, and (iii) the maximum and minimum voltage responses for each input frequency are symmetric with respect to the equilibrium point from which they are perturbed. The $I_h + I_{Nap}$ models in the parameter regimes considered here satisfy (i), but not necessarily (ii) and (iii). In Figs. 5 and 6 we illustrate the gain modes exhibited by these models.

Supra-Linear Amplification of the Voltage Response in Nonlinear Models with Parabolic-like Nonlinearities

This phenomenon is characterized by an increase in the impedance profile with increasing values of A_{in} (Fig. 5-A). The underlying dynamic mechanism has been described in Rotstein (2015, 2017c) and involves a canard-related nonlinear amplification of the voltage response due to the combination of the parabolic shape of the V -nullcline and the time scale separation between the participating variables. The

envelope of the voltage response (Fig. 5-B) is not symmetric: the upper envelope (V_{max}) exhibits a stronger change than the lower envelope (V_{min}). Both f_{res} (Fig. 5-A) and f_{phas} (Fig. 5-C) decrease with increasing values of A_{in} .

Sublinear Amplification of the Voltage Response in Nonlinear Models with Cubic-like Nonlinearities

This phenomenon is characterized by a decrease in the impedance profile with increasing values of A_{in} (red to green curves in Fig. 6-A). The underlying dynamic mechanism has been described in Rotstein (2017c). As for the previous case, the envelope of the voltage response (Fig. 5-B) is not symmetric: the upper envelope (V_{max}) exhibits a stronger change than the lower envelope (V_{min}). Both f_{res} (Fig. 5-A) and f_{phas} (Fig. 5-C) decrease with increasing values of A_{in} but the change in f_{res} during the response sublinear amplification is very small in this example.

Definition

Information theory is a practical and theoretic framework developed for the study of

communication over noisy channels. Its probabilistic basis and capacity to relate statistical structure to function make it ideally suited for studying information flow in the nervous system. As a framework, it has a number of useful properties: it provides a general measure sensitive to any relationship, not only linear effects; its quantities have meaningful units which, in many cases, allow a direct comparison between different experiments; and it can be used to study how much information can be gained by observing neural responses in single experimental trials rather than in averages over multiple trials. A variety of information theoretic quantities are in common use in neuroscience – including the Shannon entropy, Kullback–Leibler divergence, and mutual information. In this entry, we introduce and define these quantities. Further details on how these quantities can be estimated in practice are provided in the entry ► [“Estimating Information-Theoretic Quantities,”](#) and examples of application of these techniques in neuroscience can be found in the entry ► [“Applications of Information Theory to Analysis of Neural Data.”](#)

Detailed Description

Information Theoretic Quantities

Entropy as a Measure of Uncertainty

Information theory derives from Shannon’s theory of communication (Shannon 1948; Shannon and Weaver 1949). *Information*, as we use the word technically, is associated with the *resolution of uncertainty*. The underpinning theoretic concept in information theory is thus the measurement of uncertainty, for which Shannon derived a quantity called *entropy*, by analogy to statistical mechanics. Shannon proved that the only quantity suitable for measuring the uncertainty of a discrete random variable X is

$$H(X) = -K \sum_x P(x) \log_2 P(x) \quad (1)$$

where X can take a number of values x according to the probability distribution $P(x)$. The constant

K we take to be one. When the logarithm is taken to base 2, the resulting units of the entropy $H(x)$ are called *bits* (when the natural logarithm is used, the term is *nats*).

Entropy can be thought of as a nonparametric way to measure the variability of a distribution. Spread-out distributions (with high variability) will have high entropy since all potential outcomes have similar probabilities and so the outcome of any particular draw is very uncertain. On the other hand, concentrated distributions (with low variability) will have lower entropy, since some outcomes will have high probability, allowing a reasonable guess to be made about the outcome of any particular draw. In this respect, entropy can be thought of as a generalized form of variance; unlike variance, which is a second-order statistic and only meaningful for unimodal distributions, entropy can give meaningful values for any form of distribution. For a normal distribution, the differential entropy (the continuous analogue of the discrete entropy discussed here) is proportional to the logarithm of the variance, but for other types of distribution the two measures are not so closely related.

As an example, consider the roll of an unbiased six-sided die performed under a cup. With no external knowledge about the roll, an observer would believe any of the numbers are equally likely – a uniform distribution over the six possible faces. From Eq. 1, the entropy of this distribution is $\log_2 6$. Now a third party peeks under the cup and tells our observer that the die is showing an even number. This knowledge reduces the uncertainty about the result of the roll, but by how much? After being told that the die is showing an even number, the number of possibilities is reduced from six to three, but each of the even numbers remains equally likely. The entropy of this distribution is $\log_2 3$. So the reduction in the observers uncertainty, measured as the difference in entropy, is $\log_2 6 - \log_2 3 = \log_2 2$, or 1 bit. We can quantify the knowledge imparted by the statement “the result is even” as 1 bit of information. This corresponds to a reduction in uncertainty of a factor of 2 (from six to three possible outcomes). For this example, in both the before and after situations, all the possibilities were equally likely

(uniform distributions), but the methodology can be applied to any possible distribution. Note that the uniform distribution is the maximum entropy distribution over a finite set. Any other distribution would have lower entropy since it is not possible to be less uncertain about a possible outcome than when all possibilities are equally likely – there is no structure to allow any sort of informed guess. For further applications of the concept of *maximum entropy*, see the entry on ► “Estimating Information-Theoretic Quantities.”

The fact that $H(X)$ should be maximized by a uniform distribution is one of three axioms Shannon started from in order to derive the form of Eq. 1. The others are that impossible events do not contribute to the uncertainty and that the uncertainty from a combination of independent events should be the sum of the uncertainty of the constituent events. These three conditions necessarily lead to Eq. 1, although it can be reached via many other routes as well (Chakrabarti and Chakrabarty 2005).

Mutual Information

The example of a die roll motivates how a difference between entropies can quantify the information conveyed about a set of possible outcomes. In the case of two discrete random variables – here we consider S , representing a set of stimuli which are presented during an experiment, and R , a set of recorded responses – this is formalized in a quantity called the *mutual information*. This is a quantity measuring the dependence between the two random variables and which can be defined in terms of entropies in the following three equivalent forms:

$$\begin{aligned} I(R; S) &= H(S) - H(S, R) \\ &= H(R) - H(R, S) \\ &= H(R) + H(S) - H(R, S) \end{aligned} \quad (2)$$

where $H(R)$ and $H(S)$ are the individual entropies of each random variable as discussed above, $H(R, S)$ is the *joint entropy* of the two variables, and $H(R|S)$ and $H(S|R)$ are *conditional entropies*. The conditional entropy is defined as

$$H(X|Y) = \sum_y P(y) H(X|Y = y) \quad (3)$$

where $H(X|Y = y)$ is defined as in Eq. 1 but with $P(x)$ replaced by the conditional probability $P(x|y)$. The conditional entropy $H(X|Y)$ represents the average entropy of X when the value of Y is known.

The three forms of Eq. 2 above each illustrates a particular interpretation of the mutual information. From the first form, we can see that it quantifies the average reduction in uncertainty about which stimulus was presented based on observation of a response R answering the question “if we observe R , by how much does that reduce our uncertainty about the value of S ?” Equivalently, the second form shows us that it similarly answers the question “if we observe S , by how much does that reduce our uncertainty about the value of R ?” As the third form shows explicitly, mutual information is symmetric in its arguments. The third form also shows that information is the difference in entropy between a model in which the two variables are independent (given by $P(r)P(s)$ with entropy equal to $H(R) + H(S)$) and the true observed joint distribution, $P(r, s)$ (with entropy $H(R, S)$). This shows that for two independent variables, the mutual information between them is equal to zero and illustrates that information measures how far responses and stimuli are from independence.

A well known measure of difference between probability distributions is the Kullback–Leibler (KL) divergence (Kullback and Leibler 1951):

$$D_{KL}(P \parallel Q) = \sum_x P(x) \log_2 \frac{P(x)}{Q(x)} \quad (4)$$

Note that this is not a true “distance” metric since it is not symmetric – the KL divergence between p and q is different to that between q and p . As can be seen from the third expression of Eq. 2, the mutual information is just the KL divergence between the joint distribution and the independent model formed as the product of the marginal distributions:

$$\begin{aligned} I(R; S) &= D_{KL}(P(r, s) \parallel P(r)P(s)) \\ &= \sum_{rs} P(r, s) \log_2 \frac{P(r, s)}{P(r)P(s)}. \end{aligned} \quad (5)$$

In the above, S and R represent discrete random variables where one is viewed as a stimulus and the other is a recorded neural response – but these could of course be any two discrete random variables (e.g., a variable representing a wild-type vs. a genetic manipulation, behavioral responses, or other intrinsic signals). We will see shortly that information and entropy can be easily generalized to continuous signals.

A natural question is “does mutual information correspond to a measure of discriminability?” If by discriminability one means the measure d -prime (Green and Swets 1966), the answer is in general “no.” However, in the specific case where we are measuring the transmission of information about one of two equiprobable stimuli (or equivalently, presence/absence of a stimulus), mutual information has such an interpretation. This can be seen by reaching for another “distance-like measure” – this time, one that is symmetric, the Jensen–Shannon (JS) divergence, a symmetrized version of the KL divergence (Lin 1991; Fuglede and Topsoe 2004):

$$D_{JS}(P\|Q) = \frac{1}{2}D_{KL}\left(P\left\|\frac{P+Q}{2}\right.\right) + \frac{1}{2}D_{KL}\left(Q\left\|\frac{P+Q}{2}\right.\right) \quad (6)$$

It can be fairly easily seen that in the case where we have only two stimuli, s_1 and s_2 , the mutual information $I(R;S)$ can be written as

$$I(R;S) = D_{JS}(P(r|s_1)\|P(r|s_2)). \quad (7)$$

Thus the mutual information can be considered to measure how far apart (how discriminable) the distributions of responses are, given the two stimuli. Note that while mutual information generalizes to multiple stimuli, it is not entirely clear that the concept of discriminability does, in a useful way.

In summary, the mutual information is a measure of how strongly two variables are related, similar in spirit to correlation but with some

specific advantages. Firstly, it is a completely general measure; it places no assumptions or models on the variables under consideration and is sensitive to any possible relationships, including nonlinear effects and effects in high-order statistics of the distributions. Second, it has meaningful units allowing direct comparison across different experiments and even with behavioral performance. Finally, it permits several nice interpretations related to its calculation as a single trial property and involving its relationship to decoding performance.

Other Information Theoretic Quantities

Similar procedures to those used to estimate entropy and mutual information can be used to estimate a number of other information theoretic quantities. We mention several such quantities here for completeness.

Multi-information

Note that the mutual information between a pair of random variables naturally generalizes to the concept of the multivariate mutual information, or *multi-information*, the mutual information between n variables,

$$\begin{aligned} I(X_1; \dots; X_n) &= \sum_{x_1, \dots, x_n} P(x_1, \dots, x_n) \log_2 \frac{P(x_1, \dots, x_n)}{\prod_i P(x_i)} \\ &= I(X_1; \dots; X_{n-1}) - I(X_1; \dots; X_{n-1}|X_n) \end{aligned} \quad (8)$$

Note that multi-information, unlike standard mutual information, can take negative values. Multi-information has found use in neuroscience in the study of patterns of activity in neural ensembles (Schneidman et al. 2006). Note that this is not the only way to generalize mutual information beyond two variables, and a related quantity, the interaction information, can also be defined (McGill 1954; Bell 2003; Jakulin and Bratko 2003).

Conditional Mutual Information

The conditional mutual information is the expected value of the mutual information

between two variables given a third (Cover and Thomas 1991),

$$I(X; Y|Z) = H(X|Z) - H(X|Y, Z). \quad (9)$$

This quantifies the relationship between variables X and Y while controlling for the influence of Z . In neuroscience, this can be useful, for example, to investigate the coding of correlated stimulus features (Ince et al. 2012). Consider two correlated stimulus features S_1 and S_2 . If it is found that $I(R; S_1) > 0$, this could be because the response is modulated by feature S_1 , but it might be that the response is modulated by feature S_2 and the relationship between response and S_1 follows from the correlation between the features. Considering $I(R; S_1|S_2)$ can resolve this situation and reveal if the feature S_1 is truly represented.

Entropy and Information Rates

Most biological systems function not as discrete realizations from a static process (like the roll of a die), but rather operate continuously as time-varying dynamic processes. This brings to mind the notion of the *rate* at which a source generates information – e.g., if we were tossing a coin once per second and the outcomes of the coin tosses were independent, then we would be generating information at a rate of 1 bit/s. In general, the *entropy rate* of a stochastic process is defined as

$$h(X) = \lim_{n \rightarrow \infty} \frac{1}{n} H(X_1, X_2, \dots, X_n). \quad (10)$$

By extension, the *mutual information rate* is

$$i(R; S) = \lim_{n \rightarrow \infty} \frac{1}{n} I(r_1, r_2, \dots, r_n; S) \quad (11)$$

with units of bits/s. Asymptotic entropy and information rates can therefore be estimated indirectly by calculating information for sufficiently long sequences of time bins. If the calculation is repeated for smaller and smaller time bins, it is

possible to extrapolate the resulting discrete information value to the instantaneous limit, making the rate calculation independent of both sequence length and bin width (Strong et al. 1998). It is also possible to calculate them directly using a Bayesian probabilistic model (Kennel et al. 2005; Shlens et al. 2007).

Information Theoretic Quantities for Continuous Variables

The quantities above are all defined on random variables taking discrete values. However, entropy and other information quantities can also be defined on continuous spaces. In the case of entropy, replacing summation by integration yields the *differential entropy*:

$$h_{\text{diff}}(X) = \int_x p(x) \log_2 p(x). \quad (12)$$

Other information theoretic quantities can be defined analogously, in general, by replacing sums over the discrete spaces with integrals over the continuous spaces. Note that differential entropy does not entirely generalize the properties of the discrete Shannon entropy, and thus, this quantity has not been widely used in neuroscience and is therefore beyond the scope of this entry. In contrast, the Kullback–Leibler divergence and mutual information both generalize in a straightforward manner to continuous spaces. For instance, the mutual information between two random variables with joint density $p(x, y)$ is

$$I(X; Y) = \int p(x, y) \log_2 \frac{p(x, y)}{p(x)p(y)} dx dy. \quad (13)$$

Surrogate Data for Evaluation of Spike Correlation

Sonja Grün

Lab for Statistical Neuroscience, Institute of Neuroscience and Medicine (INM-6, INM-10) and Institute for Advanced Simulation (IAS-6), Research Centre Jülich, Jülich, Germany
Theoretical Systems Neurobiology, RWTH Aachen University, Aachen, Germany

Definition

In the correlation analysis of experimentally recorded parallel spike trains, one has to thoroughly consider the statistical features of the data in order to prevent false-positive results. Surrogate data, i.e., modified versions of the original spike trains, are used to assess the significance of spike correlation. The objective of surrogate data generation is to leave all statistical features of the original experimental data intact except those one wants to test for: these are to be destroyed.

Detailed Description

Generating artificial data from experimental data as a means for implementing a null hypothesis is becoming widely used. The reason is twofold: increasing computer power now allows for this type of approach, and it has become clear that the complexity of experimental data does not in general permit an analytical formulation of the null hypothesis. This is particularly true for the correlation analysis of parallel spike trains. Neglecting statistical features of experimental data such as nonstationarity of the firing of individual neurons in time or across trials, the spike train structure deviating from Poisson, or a co-occurrence of such features in parallel spike trains can lead to the occurrence of false-positive results. Problems can be avoided by including those features in the null hypothesis of the significance test. To this end surrogate data are used to generate the predictor by modifying the

original data in such a way that the feature of interest, here as an example the temporal coordination of spikes, is destroyed, but other features of the data are preserved. These data are then analyzed like the original experimental data, and the outcomes are compared (see ► “Significance Evaluation”; Harrison et al. 2013). Such data are used for bootstrap approaches in the significance estimation of the occurrence of features, e.g., spatiotemporal spike patterns (see ► “Statistical Evaluation of Spatio-temporal Spike Patterns”). In the case of precise joint spike events (see ► “Unitary Event Analysis”), the interest is to keep the statistical features of the spike trains of the individual neurons as similar to the original as possible but to destroy the exact relative timing of spikes from different neurons (for a comprehensive list of references, see Grün (2009) and Louis et al. (2010a, b)).

Modeling spike trains as stochastic processes is an elegant way to generate surrogate data. Often used are inhomogeneous Poisson processes that reproduce the dynamics of the firing rate according to the estimated firing rate profiles. More complicated processes which in addition reproduce the interspike interval (ISI) or higher-order interval statistics or even change their internal structure as a function of time can be modeled (see ► “Population Encoding/Decoding,” ► “State-Space Models for the Analysis of Neural Spike Train and Behavioral Data,” and ► “Generalized Linear Models for Point Process Analyses of Neural Spiking Activity”). Although often not all parameters can be estimated from the experimental data, a formal characterization of neuronal spiking dynamics (the stochastic model) is helpful since it constitutes a precise description of the assumptions. Consequently, it enables more specific statements about the experimental data.

Other methods for generating surrogate data operate directly on the original data and modify them according to specific rules. Spike time randomization, i.e., random shuffling of the spikes of a neuron within a given time interval, assumes stationary rate within the window (Fig. 1, red). The procedure is closely related to the generation of a stationary Poisson process, but here the spike counts are additionally matched. The ISI structure

Surrogate Data for Evaluation of Spike Correlation, Fig. 1 Comparison of original and surrogate cross-correlograms (CCHs) (see ► “Correlation Analysis of Parallel Spike Trains”). The CCH of an original data set (black), composed of two neurons simulated with background firing activity as nonstationary co-modulating gamma processes, inhomogeneous across trials (40 trials), with additionally injected coincident spike events (rate: 3 Hz, coincidence width: ± 1 ms). Surrogate CCHs are generated by trial shuffling (*tr-shu*, blue), by spike time randomization (*sp-rnd*, red), or by spike dithering (*sp-di*, cyan) and are shown as the mean over 1,000 surrogates (thin lines) and the mean plus twice the standard deviation over the surrogates (thick lines). Only the surrogate CCH based on dithering reproduces well the overall shape of the original CCH reflecting chance coincidences due to the firing rates but destroys the narrow central peak due to correlated activity. The other two surrogates underestimate the chance coincidences and thus may lead to false-positive results in independent data of the same rates but without correlated spike events. (Modified from Louis et al. 2010b)

of the original data, however, is destroyed. Other methods particularly focus on the conservation of the ISI distribution by shuffling the ISIs of a neuron within a trial, thereby simultaneously preserving the spike count of each trial. Furthermore, a potential covariation of spike counts across neurons is automatically preserved. In attempts to additionally account for nonstationarity in time, ISI shuffling may be performed in shorter time windows across trials, which, however, assumes cross-trial stationarity.

Trial shuffling is a way of destroying the relationship between simultaneously recorded spike trains. Trial data of one neuron are randomly assigned to trials of other neurons, thereby destroying potential spike correlation but leaving the internal structure of the spike trains and thus the spike counts intact. Potential covariation of spike counts across the neurons is thereby destroyed. Thus, nonstationarity across trials cannot be tolerated, since a recombination of these features, e.g., rate, may additionally change the chance occurrence of joint spike events (Fig. 1, dark blue). For the shift predictor, spike trains are not randomly assigned, but trial IDs of the two neurons are shifted systematically against each other. The shift predictor is mainly of historical interest as an approximation to the full shuffle. However, e.g., in the presence of slow changes of statistical features across trials, the shift predictor may still be favorable.

Surrogate methods based on exchanging or randomizing spikes across neurons within the same trial may serve well for the evaluation of spatiotemporal spike pattern (see ► [“Spatial Temporal Spike Pattern Analysis”](#)). These surrogates preserve the population histogram of each trial but preserve neither the PSTHs nor the ISI distributions and assume co-stationary data.

Spike dithering, often also called jittering or teetering, i.e., independent randomization of the individual spike times within a small predefined time interval, destroys the exact spike timing and therefore also exacts relative spike timing across the neurons (see ► [“Statistical Evaluation of Spatio-Temporal Spike Patterns”](#)). This effectively leads to some smoothing of the firing rates and also to a slight modification of the ISI distribution (Fig. 1, cyan). The latter can be minimized by weighting the dither according to the joint interspike interval distribution.

However, if firing rates change strongly on a short time scale, the smoothing effect of dithering becomes stronger, which in turn tends to lead to false-positive results. Therefore, it was suggested to first transform the data by time rescaling according to the firing rate into operational time, such that firing rates become stationary. Dithering is then applied in this representation. After transformation back into the original representation,

joint spike events are detected. Even for strong rate changes, this surrogate method does not introduce false positives (Louis et al. 2010a).

Instead of modifying the individual spike times, it was suggested to shift the complete spike trains, or parts of it, against the others by random amounts (Amarasingham et al. 2012; Pipa et al. 2008; Wu et al. 2011). Thereby the structure of the spike trains or large parts of them are conserved; only the PSTHs are smoothed depending on the maximal shift. To have an effective destruction of joint spike events, the maximal shift needs to be chosen by a factor larger than the temporal precision of the joint spike events. This variant of dithering seems to be most appropriate to account for the features of the single-neuron statistics and can also be done in operational time (Louis et al. 2010a).

The creation of surrogate data is an attractive way to generate control data and is conceptually simple. However, for a proper choice of the surrogate, one has to be clear about the implicit assumptions and affected spike train features. This implies that the choice of surrogate may depend on the correlation analysis method used and that a particular surrogate method needs to be tested in the context of the intended analysis.

Definition

Synaptic connectivity refers to the ensemble of direct chemical and electrical connections between neurons. In chemical synapses afferent presynaptic neuroelectric activity is mediated via neurotransmitters to the postsynaptic terminal, at which the postsynaptic activity can be either increased or decreased as a function of the excitatory/inhibitory character of the synapse. In electrical synapses the presynaptic and postsynaptic cell membranes are connected by special channels called gap junctions that are capable of directly passing electrical current between neurons. In neural population models the various aspects of synaptic connectivity are absorbed, typically through mean field techniques, by connectivity functions, parameters, and/or nonlinear response functions.

Detailed Description

A synapse is a connecting structure that permits a (presynaptic) neuron to pass an electrical or chemical signal to another (postsynaptic) neuron. There are hence two fundamentally different types of synapses: chemical and electrical synapses.

In a chemical synapse, electrical activity in the presynaptic neuron is converted (via the activation of voltage-gated calcium channels) into the release of a neurotransmitter that binds to receptors located in the postsynaptic cell. The binding

process of the neurotransmitter initiates an electrical response on the postsynaptic neuron that may either depolarize (excitation) or hyperpolarize (inhibition) the postsynaptic neuron. The process of presynaptic neurotransmitter release, migration through the synaptic cleft, and binding on the postsynaptic side requires time, and its time course is characteristic of different neurotransmitter types giving a range of fast synapses (GABA_A, AMPA) to slower synapses (GABA_B, NMDA). Models of synaptic dynamics are typically nonlinear and expressed through ordinary differential equations involving transmitter concentration and release time, conductance strength, or reuptake time (Destexhe et al. 1994). Synaptic couplings between neurons are effectively of nonlinear and multiplicative nature. The time of synaptic transmission delay. Kinetic models of synaptic transmission are often used in the modeling of network dynamics (Destexhe 1998), as they provide a good compromise of accurate level of biological detail and computational efficiency. A simpler model of synaptic transmission is the so-called alpha function, which captures the time course of the postsynaptic response to a delta-spike (Gerstner and Kistler 2002).

In an electrical synapse, communication is electrically conductive through the cell's membrane and considered nearly instantaneous; thus, its transmission delay is negligible. Mathematically symmetric linear difference couplings between pre- and postsynaptic neurons are based on Kirchhoff's current law and alter the respective neuronal membrane voltages. Electrical couplings between neurons are effectively of linear nature.

On the neural population level, synaptic coupling is the predominant connectivity considered. Neural population models that were derived from single neuron models (such as Brunel and Wang (2003), Wong and Wang (2006), Stefanescu and Jirsa (2008, 2011)) preserve the nonlinear nature and time scales of the synaptic couplings. Neural population models that were not derived from a microscopic level, but were rather being posed ad hoc, typically absorb the coupling's (spatial, temporal, (non)linear) effects in the nonlinear population response function and then rely on additive

linear couplings between neural populations (such as Wilson and Cowan (1972, 1973), Nunez (1974), Jirsa and Haken (1996), Robinson et al. (1997)). Excitatory coupling then enters as an input that increases the rate of the neural population's activity and inhibitory coupling decreases its activity. This procedure has been justified in Jirsa and Haken (1996) by the conversion properties of synaptic activities (wave) and firing rates (pulse) on the population level. Walter Freeman (1975) demonstrated that these population measures show robust dependencies; in particular wave-to-pulse conversion is highly nonlinear showing saturation, whereas the pulse-to-wave conversion is limited to the linear regime.

Other means of introducing features of synaptic connectivity into neural population models are through manipulations of the axonal propagator. A plus and minus sign may be assigned to the distribution of connection weights (see, for instance, Amari (1977)) to create coupling functions such as the Mexican hat function with central excitation and lateral inhibition. The latter has been shown to be essential for the realization of self-sustained spatial patterns thought to be involved in working memory. Local circuits of mutually coupled populations via excitatory and inhibitory connections are well known to give rise to the emergence of rhythmic firing patterns. To characterize the time scales of synaptic processes in neural fields, linear convolutions have been introduced postsynaptically to modulate the effects of axonal propagation (see (Hutt and Atay 2005) for treatments of gamma-distributed synaptic footprints). Plasticity changes of synaptic connectivity rely on the timing of pre- and postsynaptic neuronal discharges and are established in cellular models of neurons (Abbott and Nelson 2000), but less well understood on the population level.

Synthetic Neuronal Circuits/Networks

Padraig Gleeson

Department of Neuroscience, Physiology and Pharmacology, University College London, London, UK

Definition

Processing of information in neuronal networks involves communication between cells with complex dendritic and axonal arbors, belonging to multiple populations each having characteristic firing properties. This complex 3D structure, where synaptic connectivity between groups of cells can also be restricted to specific anatomical

layers, is believed to be an important determinant of network behavior.

While many initiatives aim to reconstruct the full connectome of specific brain regions by mapping each neuron and synaptic connection in a block of tissue, other approaches take existing information on the known cell types and their overall connectivity rules and attempt to generate synthetic neuronal circuits from these. This can be useful for checking the completeness of knowledge of the circuit and to provide input to large-scale simulations of network behavior.

Detailed Description

Reconstructed and Synthetic Neurons

Recent developments in the field of connectomics are paving the way toward having access to the complete wiring diagram of specific networks in the brain. These will comprise full 3D reconstructions of all cells in the network along with all of the synaptic locations. Significant progress has been made on the complete neuronal wiring diagrams for simple species (White et al. 1986), but even a fully reconstructed cortical microcircuit from a mammalian brain is many years away. However, some regions such as the retina (Helmstaedter et al. 2013) have already been studied in greater detail than previously possible with these methods.

For many regions however, while no complete wiring diagrams exist, plenty of statistical data is available on the overall anatomical layout of the neuronal circuitry, the types of cells present, their densities in specific layers, overall morphological features of the cell classes, connection probabilities between cell populations, as well as electrophysiological properties of the cells and synapses. This has led to various attempts to create synthetic versions of such circuits from these data, both as a means of cataloging what's known about the structure and connectivity of specific brain regions and for creating *in silico* models of the networks. These models can be used to gain a greater

understanding of the networks through visualization or simulation of their electrical activity.

Simplified Synthetic Networks

Many point neuron network models (e.g., using leaky integrate and fire neuron models or two state variable extensions of this (Izhikevich 2003; Brette and Gerstner 2005)) have been created which seek to examine general operating principles of generic neural networks (Brunel 2000). Increasingly however, abstract network models are being created which incorporate data from specific brain regions on the specific cell types present, their relative densities/soma locations, and connectivity. A recent example is Potjans and Diesmann (2012), which describes a full-scale anatomically constrained model of the local cortical microcircuit using integrate and fire neurons. This can reproduce various experimentally observed features of the circuit including layer-specific cell activity patterns and propagation of transient thalamic inputs.

Conductance-based cell models aim to explain the firing patterns of cells in terms of the ion channels known to be present on the cell membrane. A number of anatomically inspired network models have been created taking this approach, often built up from detailed studies of single-cell properties. Solinas et al. (2010) describe a 3D model of the granule cell layer of the cerebellum incorporating conductance-based models of granule and Golgi cells. This network has been used to study not only temporal signal processing but also the spatial spread of activity following focused synaptic input.

Another example of an anatomically and electrophysiologically constrained network model of a distinct brain region is that of the dentate gyrus in Santhakumar et al. (2005). This contains reduced (9–17 compartments) multicompartmental models of granule, basket, HIPP, and mossy cells from this region and investigates how changes in cell number and connectivity following head trauma can lead to network

hyperexcitability. This model is being used as the basis for a much larger-scale model which will incorporate cell numbers in line with the actual rat dentate gyrus (Schneider et al. 2012).

The single-column thalamocortical network model of Traub et al. (2005) is one of the most detailed network models produced to date, featuring 14 cell types from the thalamus and multiple layers of the cortex, tuned to cell-type-specific firing behavior and incorporating known patterns of layer-specific synaptic connectivity. While this model too has reduced numbers of compartments in each of the cells (~80), it still requires the use of parallel computing resources to run. However, it represents a useful middle ground between more abstract cortical models and the highly detailed simulations used, for example, in the Blue Brain Project (see below), incorporating as it does sufficient detail to ask detailed questions about the contribution of specific cells, ion channels, and synaptic properties to network function, on computing resources which would be available to most researchers.

Synthetic Networks with Morphologically Detailed Cells

While abstract cells with reduced numbers of compartments are useful for generating, analyzing, and simulating large-scale networks, there is a growing need to use more morphologically realistic neurons to examine the full range of computations possible in single cells (Silver 2010) and networks. Using morphologies of reconstructed cells is an option due to the availability of databases of these (e.g., NeuroMorpho.org; Parekh and Ascoli 2013). For network analyses, however, there are usually not sufficient numbers of reconstructions of cells of given types to create a realistic network without using multiple, morphologically identical cells in a network. Generating a set of synthetic cells with similar morphological properties to reconstructed cells is a possible route toward more realistic large-scale models (Evans and Polavaram 2013).

TREES toolbox (Cuntz et al. 2010; ► [TREES Toolbox: Code for Neuronal Branching](#); <http://www.treestoolbox.org>) is an application which has various features which can help address this. While it can be used for semiautomated reconstruction of cells from image stacks, it also allows generation of new morphologies based on extracted features of cells or groups of cells (e.g., 3D densities of branch points). This can potentially be used for generating multiple different cells of a particular class for use in network models. NETMORPH (Koene et al. 2009; <http://netmorph.org>) is an application which can also be used to generate synthetic neurons. It is based on the growth of neurons, with rules for how neurites should elongate, branch, and turn in 3D. Neural networks can be created based on the proximity of axonal and dendritic sections. NeuGen (Eberhard et al. 2006; <http://atlas.gcsc.uni-frankfurt.de/%7Eneugen>) is a similar tool with a focus on generating 3D networks of specific cortical regions (e.g., cortex, hippocampus) using rules extracted from morphological features of the cells present in those regions. Cx3D: Cortex Simulation in 3D (Zubler et al. 2013; <http://www.ini.uzh.ch/%7Eamw/seco/cx3d>) is a tool for simulating the growth of neural tissue, not only the growth of axons and dendrites in confined 3D spaces but also movement of cells. Chemical gradients can be added which influence the movement of specific entities. A recent version of this tool allows execution across multiple processors speeding up the generation of large-scale networks. More details on the different strategies and algorithms used for generation of synthetic neuronal morphologies can be found in this article.

A comparison of a number of the tools mentioned above is presented in Ćimović et al. (2011). Each of these tools has a slightly different focus and may be more or less appropriate for use depending on the research question to be addressed. None is a simulator of electrophysiological network activity; instead, they concentrate on exporting to other formats making it easier to simulate such behavior. Export to NeuroML

(Gleeson et al. 2010) is supported by TREES toolbox and CX3D (and is also an option at NeuroMorpho.org) allowing generated networks to be imported into simulators like NEURON and visualized/analyzed by other applications, e.g., neuroConstruct (Gleeson et al. 2007).

Large-Scale Simulations of Synthetic Networks

A number of initiatives have started to look at the generation of simulations of morphologically detailed neural networks at the scale of macroscopic brain regions. The Neural Tissue Simulator (Kozloski and Wagner 2011) aims to make it possible to simulate a whole block of neural tissue by efficiently segmenting the region into sections, each of which is simulated on a separate processor in a parallel environment. There is initiative to reconstruct and simulate the rodent barrel cortex (Egger et al. 2012), which is developing new methods to register cell morphologies obtained from different animals against a common anatomical reference frame. The Blue Brain Project (<http://bluebrain.epfl.ch>) has been gathering data and developing methods for creating a simulation of a complete cortical column for a number of years. This work will continue as part of the 10-year EU-funded Human Brain Project (<https://www.humanbrainproject.eu>).

More details on software applications for creating detailed models of neuronal systems can be found in the entry ► “Software Tools for Modeling in Computational Neuroscience: Overview.”

Conclusions

While initiatives to reconstruct the complete wiring diagrams of various species or brain regions are gaining pace, there is much that can be learned by consolidating the vast amounts of data on different brain regions into models, both describing the structure and connectivity of the networks and potentially allowing detailed simulations of the activity of the cells. This task is larger than one lab can manage on its own, and a key part of this

process will be the availability of appropriate software tools and databases required to construct such models. Thankfully, more and more resources are becoming available for sharing data on neurons and their properties (e.g., ► [NeuroMorpho.org](#), ► [NeuroElectro Project](#), SenseLab: Integration of Multidisciplinary Neuroscience Data; Bezaire and Soltesz 2013) and for sharing models (► [ModelDB](#), ► [Open Source Brain](#)) and the software required to simulate them (► [Software Tools for Modeling in Computational Neuroscience: Overview](#)).

Algorithms for generating neuronal morphologies; Morphogenetic algorithm; Virtual neuron generation

Definition

A synthetic neuronal morphology is a digital representation of a neuron's morphology that is not acquired experimentally but rather generated by an algorithm. The input to such an algorithm is often a prototype, experimentally reconstructed morphology (or a set thereof). A synthesis algorithm then incorporates this prototype data in some way to generate a new digital reconstruction from scratch. Thus, synthetic neurons are *de novo*, algorithmically created digital reconstructions not originating directly from experimental data.

History of Synthesizing Neuronal Morphologies

Since the pioneering work of Golgi to visualize neurons *in vitro* and the subsequent beautiful drawings by Ramon y Cajal, neuroscientists have been fascinated by neuronal morphologies. The attempt of Hillman (Hillman 1979) to quantify neuronal morphologies kick-started the field investigating synthetic morphologies. Hillman described a set of so-called fundamental parameters that were sufficient to describe neuronal morphologies. Hence, the idea for later sampling algorithms to synthesize morphologies was born: if there exist a set of fundamental parameters that adequately capture morphologies, you can, in principle, sample from the statistical distribution of these parameters to create a new morphology that shares statistical properties with the original.

However, it took another decade before the first algorithms were presented to synthesize morphologies. One set of algorithms was based on the ideas of Hillman to sample from statistical distributions of parameters describing morphologies (Burke et al. 1992; Nowakowski et al. 1992). The other algorithms were based on L-systems (Pellionisz 1989; Hamilton 1993; McCormick and Mulchandani 1994). An L-system or Lindenmayer system is a mathematical formalism to generate recursively branched structures that had been successfully applied earlier to synthesize digital representations of botanical trees (Lindenmayer 1968). Quantification of morphologies per se also generated many insights, which resulted in rigorous descriptions of morphologies (for instance, Uylings et al. 1986; Van Pelt et al. 1992; Tamori 1993). These combined efforts lead to a synergy between L-systems and solid quantification of fundamental parameters that accumulated in L-Neuron (Ascoli and Krichmar 2000), a sampling algorithm implicitly implementing a stochastic L-system to create a topology while relying on sampling from fundamental parameters to create a geometry. L-Neuron has become the most visible tool for the synthesis of neuronal morphologies.

Around the same time, due to advances in computational resources and recording techniques, the interest in dendritic morphologies

and their role in computation grew (Traub et al. 1991; De Schutter and Bower 1994). Because of the labor-intensive nature of experimentally reconstructing morphologies, many algorithms to synthesize neurons were proposed (see next section). This recent *raison d'être* contrasts with the historical reason to algorithmically generate morphologies, namely, as a testing bed to investigate hypotheses about morphological traits and their variance.

Detailed Description

Today, there are many different types of algorithms to synthesize neuronal morphologies. Most of them are specifically designed to study or mimic a particular characteristic of neurite morphology. Consequently, any classification of the algorithms is inherently artificial and post hoc. But a classification creates order and increases understanding. Therefore, the algorithms are here classified into two categories: context-independent and context-dependent ones. Clearly, neurons do not grow in a vacuum but rather take their shape from interactions with the neuronal matrix, i.e., their context (Jan and Jan 2010). But treating neurons as if they were in a vacuum makes their study more straightforward; and hence, this abstraction is widely adopted.

Context-Independent Algorithms

Sampling Algorithm

Most current algorithms are instances of the so-called sampling algorithms briefly introduced before and treat morphologies as if they were floating in a vacuum. Sampling algorithms start with a statistical description of fundamental parameters, i.e., a set of parameters that is considered sufficient to fully describe a neuronal morphology (Hillman 1979). Then, they iteratively synthesize a morphology by sampling features of the morphology under construction from the statistical model (Burke et al. 1992; Tamori 1993). The majority of morphology synthesis algorithms are of the “sampling type” and one of the best

known implementations is L-Neuron (Ascoli and Krichmar 2000). Differences between sampling algorithms are manifested in different characteristics of the algorithms. Firstly, the statistical descriptors can be parametric (Ascoli and Krichmar 2000; Eberhard et al. 2006) or nonparametric (Lindsay et al. 2007; Torben-Nielsen et al. 2008). In parametric models, the researcher has to define the type of distribution that best fits the prototype data (e.g., a Gaussian distribution parametrized by its mean and standard deviation). This can be an advantage when there is little data available, and human judgment is needed to see the true distribution in the data. Nonparametric statistical models on the other hand do not make any assumptions on the type of distribution underlying the data. As such, the researcher using these models does not impose a bias on the distribution, and thus, in principle, the data is described more accurately (Torben-Nielsen et al. 2008). Also, the selection and description detail of the fundamental parameters can be different: fundamental parameters can be considered independent from each other (e.g., a univariate description) or dependencies can be introduced by using multivariate descriptions (Burke et al. 1992; Ascoli and Krichmar 2000; Torben-Nielsen et al. 2008). For instance, the segment length can be considered to be independent of other features (=univariate) or dependent on the topological order (=bivariate) or on the topological order and the Euclidean distance to the soma (=trivariate). Generally, these dependencies are tuned to achieve the best match between prototype and de novo data.

Growth Algorithm

One of the very first algorithms to synthesize parts of the dendritic structure is developed by van Pelt and colleagues (van Pelt et al. 1986; Uylings et al. 1986; van Ooyen 2001). Initially, they aimed at quantifying dendritic branching patterns. To this end, they developed an algorithm to synthesize dendritic topologies that captured experimentally observed variation. The algorithm is based on the simultaneous extension of growth cones and uses probabilities conditioned on the local branching order to decide the fate of a cone: elongate, bifurcate, or terminate. They demonstrated that

plausible branching patterns of distinct morphological classes could be generated solely based on differential dependencies on branch order and the number of growing cones at any moment. Only recently, they extended their models to include a geometrical component that spatially embeds a dendrite topology into 3D, i.e., complete synthetic morphologies. The NETMORPH simulator can now be used to grow large networks of morphological model neurons (Koene et al. 2009).

Context-Dependent Algorithms

Interactions Through Competition over Resources

A straightforward way to introduce interactions between synthetic neurons is by growing them simultaneously and having them compete of “resources.” A first attempt to capture competition over resources and its influence on morphology was reported in Nowakowski et al. (1992). However, they extracted the hypothesized influence of competition and inserted it as a rule into generated single morphologies. The approaches listed below synthesize multiple truly interacting morphologies.

An approach based on diffusion-limited aggregation was developed by Luczak (2006) and aimed at investigating the role of competition over resources on dendritic morphology. In his approach a developing morphology starts out as a seed located in a bounded space. Inside the bounding space, “neurotrophic particles” randomly move around and adhere to the seed (a 1-particle aggregate) and hence expand the developing morphological structure (to an $n + 1$ aggregate). The final morphology is obtained when all particles are aggregated into the synthesized morphology. By starting with several seeds in a bounded space, the growing morphologies compete over the resources (e.g., neurotrophic particles) and interactions between developing morphologies emerge. He showed that only by varying the bounding space and the initial distribution of neurotrophic particles, dendrites of distinct morphological classes could be synthesized. The resultant claim is therefore that morphologies can be interpreted as being shaped exclusively by

environmental interactions through competition and without the need of detailed statistical descriptors.

A different approach is developed by Cuntz et al. (2010) who first analyzed the tree structure of dendrite morphologies as well as functional implications of the dendritic diameter on voltage propagation in neurons. Based on these findings they proposed an algorithm in which “points of interest” are drawn from a distribution describing the density of the dendritic field before connecting these points by a modified minimal spanning tree (MST) algorithm. The modification consists of the introduction of a balancing factor so that not only the total wiring length (as in a pure MST algorithm) is taken into account but also the path length to the soma. Diameters are assigned during a post-processing step. The main advantage is that the algorithms have a direct biological interpretation in terms of one of the functions of dendrites, namely, its role in collecting inputs. Suppose that the sampled points of interest represent synapse (i.e., axonal boutons). Then, Cuntz’s approach is based on synthesizing a morphology that samples these inputs under the biological parsimony constraint (Cuntz 2012). By growing multiple morphologies at the same time in the same volume, competition occurs and shapes the morphologies.

Growth in the Midst of Attractors and Repellents

Other approaches are developed specifically with the goal of capturing environmental interactions that underlie biological growth of neurons (Scott and Luo 2001; Jan and Jan 2010).

One of the first to generate dendrite morphologies based on environmental interaction were Samsonovich and Ascoli (2003). In their work they studied factors that influenced the direction of growth of neurons. They found that the strongest factor influencing the direction was the location of the soma: pyramidal cells seem to grow away from their somata. Subsequently, they constructed a synthesis algorithm based on a hidden Markov model that computed the direction of growth of dendritic branches and found that the virtual dendrites had a

similar spatial embedding as their biological counterparts (Samsonovich and Ascoli 2005).

A slightly more detailed proposal involved a context-dependent L-system to model axon guidance under environmental cues (Feng et al. 2005). Rather than to sample the parameters for the L-system (as in L-Neuron), the values for the parameters are computed depending on the context, i.e., the modeled neuronal substrate containing attracters and repellents exerting influence on the speed of growth and direction. In the substrate, attracters and repellents were placed by the researcher and the developing axon queried their locations.

A recently developed approach by Memelli et al. (2013) explicitly uses environmental interactions to grow dendritic morphologies. In their approach, the topology is generated according to a straightforward bifurcation process (i.e., Galton-Watson process; Uemura et al. 1995). The geometry, however, is wholly based on environmental cues. Cues are then used to bias the growth direction. As a proof of principle they demonstrated how self-referential cues, that is, cues generated by the neuron itself (i.e., inertial stiffness, somatic repulsion, and self-avoidance), can readily synthesize dendrites of different neuronal classes. So far the environmental interaction is thus limited to interactions within the neuron being generated. However, a cue coming from another neuron is conceptually identical to a cue coming from the neuron itself: it is a bias on the direction of growth. Hence, this approach does not require statistical descriptors and morphologies emerge from environmental interactions.

The most elaborate approach in this category of synthesis algorithms, CX3d, is developed by Zubler and Douglas (2009). They developed a framework in which neurons can grow in accordance to growth rules that allow interaction with the environment. Each growth cone contains the growth rules for this neuron encoded in a gene-like format (Zubler et al. 2011). The growth rules may use environmental cues such as chemical gradients or other contextual information. In addition, a growing neurite can leave cues as it grows

and switch on or off growth rules depending on its environment. With this setup, many of the complexities of cortical circuits can be modeled (at least at a phenomenological level).

The list of treated synthesis algorithms is not an exhaustive list of proposed synthesis algorithms. Rather the aforementioned approaches illustrate a tendency in the development of such algorithms directing away from purely statistical, context-independent approaches towards context-dependent approaches that use biophysical mechanisms (albeit phenomenological) to generate morphologies.

Outlook

Neuronal morphologies are receiving increasing attention because of improved experimental techniques to visualize and manipulate neurons at the level of dendrites and axons and because the influence of dendritic morphology on neuronal processing in normal (Silver 2010; London and Häusser 2005; Koch and Segev 2000) and pathological cases (Emoto 2011; Moolman et al. 2004; Irwin et al. 2000) is becoming more apparent. Consequentially, a great deal of effort is invested in identifying genetic and transcription factors that underlie the formation of neuronal morphologies. These studies already resulted in better knowledge of transcription factors involved in neuronal self-avoidance, tiling, and space filling (e.g., Scott and Luo 2001; Jan and Jan 2010). Such knowledge will harness a big leap forward in the synthesis of neuronal morphologies and their variation, because, finally, neurons do grow in interaction with other neurons and agents in the neuronal matrix.

Definition

SBML (the Systems Biology Markup Language, <http://sbml.org>) is a representation format designed to enable software systems to communicate and store computational models of biological processes. It is not intended as a universal language for quantitative models; rather, SBML's purpose is to serve as a *lingua franca* for exchanging the essential aspects of a computational model between widely different software systems and databases.

Detailed Description

A vast number of modeling and simulation software tools are available today for research in biological domains such as computational neuroscience. This wealth of resources is a boon to researchers, but it also presents interoperability problems. Different software tools for systems biology are implemented in different programming languages, run on different operating systems, express models using different

mathematical frameworks, provide different analysis methods, present different user interfaces, and support different data formats. Despite working with different tools, researchers want to disseminate their work widely, as well as reuse and extend the models of other researchers. They do not want to hardcode their models as software programs nor assume everyone uses the same computing environment; they need common exchange formats for representing their models in such a way that a variety of software systems can read and write them.

SBML (the Systems Biology Markup Language) is such an exchange format for communicating and storing computational models of biological processes (Hucka et al. 2003). It is not a universal language for representing all possible models; rather, it enables communication of the essential aspects of a model, together with annotations that permit any aspect of the model to be elaborated and linked to external data resources. An important principle in SBML is that models are decomposed into explicitly labeled constituent elements (e.g., substances involved in processes, compartments where they are located, etc.); models are *not* cast directly into a specific form such as differential equations. This abstract approach makes it possible for a software tool to translate the SBML form of a model into whatever internal form the tool actually uses – whether that be differential equations, stochastic systems, or some other framework. Although SBML has its roots in general simulations of biochemical reaction networks, it can be used more generally to express other types of models where biological entities are involved in, and modified by, processes that occur over time. It is used today in research on a number of topics, including cell signaling pathways, metabolic pathways, biochemical reactions, gene regulation, and many others.

The latest generation of SBML, which is called SBML Level 3, is modular in the sense of having a defined core set of features and optional *packages* that add features on top of the core. This modular approach means that models can declare which feature-sets they use, and likewise, software tools can declare which packages they support. It also means that the development of SBML Level 3 can proceed in a modular fashion. SBML Level

3 package development is today an ongoing activity, with packages being created to extend SBML in many areas that its core functionality does not directly support. Examples include models whose species have structure and/or state variables, models with spatially nonhomogeneous compartments and spatially dependent processes, and models in which species and processes refer to qualitative entities and processes rather than quantitative ones.

Tactile Sensing in Insects

Volker Dürri and André F. Krause
Bielefeld University, Bielefeld, Germany

Definition

The sense of touch, or tactile sense, belongs to the modality of *mechanoreception* and, more specifically, *somatosensation*. It is an exteroceptive sense that encodes information about physical contact events between a body part and an external object, thus informing the animal about object location, shape, and texture. In insects, the major organs for tactile sensing are the antennae (or feelers), although most body parts carry

mechanoreceptive sensilla, too. Antennae are segmented, actively moveable appendages of the head. Despite the actuation, the antennae are held still in some tactile sensing behaviors (passive sensing), whereas in others they are moved actively (active sensing).

Detailed Description

Passive and Active Tactile Sensing Behaviors

Insect antennae can have very different shapes, with the shape reflecting their use in behavior. Antennae serve other sensory modalities than touch, too (e.g., smell and taste). Generally, insects with elongate, unbranched antennal segments use them for tactile sensing during locomotion. For course control, e.g., in flying bees or running cockroaches, antennae are held relatively still at a constant angle, essentially serving as passive sensors for measuring wind speed or lateral clearance (e.g., distance to a wall, Camhi and Johnson 1999). During walking, antennae are often moved rhythmically, thus actively sampling the near-range environment. In such tactile exploration behavior, antennae serve as active sensors. Active exploration movements consume energy but allow sampling of a 3D volume, thus improving information gain. If, as in stick insects, the joint axis orientation vectors of the antennal joints are known, this searching movement can be

analyzed at the level of individual joint movements (e.g., Krause et al. 2013). Upon antennal contact with an obstacle, the typical searching pattern of antennal movement changes into a sampling pattern with different properties, e.g., higher cycle frequency and lower amplitude (Krause and Dür 2012). By means of active tactile sensing, insects can localize obstacles or potential foothold locations in space and respond by appropriate leg movements (Schütz and Dür 2011), whole-body orientation (Okada and Toh 2006), or make decisions about obstacle negotiation (Harley et al. 2009). Active tactile sensing with antennae also occurs in non-locomotion behaviors, for example, in aggressive behavior of crickets. For a review of antennal mechanoreception in various behaviors, see Staudacher et al. (2005).

Sensors Involved in Tactile Localization and Movement Control

Contact location along the antenna is sensed by thousands of sensilla, many of which contain mechanoreceptors (see Staudacher et al. 2005, for review of antennal mechanoreceptors). For spatial localization of a contact site, additional information is required about the antennal posture. Indeed, several proprioceptors encode postural information about antennal orientation or bending direction. These comprise a strand receptor in the head capsule (Bräunig 1985), hair fields at the two antennal joints (e.g., Okada and Toh 2000; Krause et al. 2013), and strain-encoding campaniform sensilla (e.g., Heinzel and Gewecke 1979). Encoding properties of these proprioceptors are best studied for hair fields, which encode both positional and velocity components (Okada and Toh 2001).

Kinematics of Antennal Movement

Most insect species (the *Ectognatha*, a group comprising all winged and secondarily wingless insects) have only two true antennal joints. One of them connects the head capsule to the scape (first antennal segment; synonym: Scapus), the other connects the scape to the pedicel (second antennal segment; synonym: Pedicellus). The distal flagellum cannot be moved actively relative to the pedicel, since only the head capsule and the scape contain muscles. In many insect species, like crickets, locusts, and stick insects, both antennal joints have only a single degree of freedom of motion (DoF), i.e., they function as hinge joints (Fig. 1). In this case, there is a unique set of joint angles for any antennal pointing direction. Accordingly, the inverse problem is solvable, too: the joint angles can be calculated from the 3D pointing direction, provided the joint axis vectors are known (see Krause and Dür 2004, for inverse kinematics of antennae with two hinge joints).

Given the resting position of the antennal tip, $\mathbf{p}_{\text{rest}}$, relative to the SP joint, the resting position of the SP joint, $\mathbf{p}_{\text{SP}}$, relative to the HS joint, and the orientation vectors of both joints, $\mathbf{r}_{\text{HS}}$ and $\mathbf{r}_{\text{SP}}$, the position of the antennal tip given the joint angles α and β (direct kinematics) is

$$\mathbf{p}(\alpha, \beta) = \mathbf{R}(\alpha, \mathbf{r}_{\text{HS}})\mathbf{T}(\mathbf{p}_{\text{SP}})\mathbf{R}(\beta, \mathbf{r}_{\text{SP}})\mathbf{T}(\mathbf{p}_{\text{rest}})(0, 0, 0, 1)^T,$$

where $\mathbf{R}(\varphi, \mathbf{r})$ is a homogeneous rotation matrix describing the rotation around joint axis $\mathbf{r} = (r_x, r_y, r_z)$ by angle φ , and $\mathbf{T}(\mathbf{v})$ is a homogeneous translation matrix describing a shift by vector $\mathbf{v} = (v_x, v_y, v_z)$ within the reference coordinate system.

$$\mathbf{R}(\varphi, \mathbf{r}) = \begin{pmatrix} \cos \varphi + r_x^2(1 - \cos \varphi) & r_x r_y(1 - \cos \varphi) - r_z \sin \varphi & r_x r_z(1 - \cos \varphi) + r_y \sin \varphi & 0 \\ r_x r_y(1 - \cos \varphi) + r_z \sin \varphi & \cos \varphi + r_y^2(1 - \cos \varphi) & r_y r_z(1 - \cos \varphi) + r_x \sin \varphi & 0 \\ r_x r_z(1 - \cos \varphi) - r_y \sin \varphi & r_y r_z(1 - \cos \varphi) - r_x \sin \varphi & \cos \varphi + r_z^2(1 - \cos \varphi) & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

Tactile Sensing in Insects, Fig. 1 *Left: Top view of a stick insect head. The left antennal segments are labeled with Sc for scape, Pd for pedicel, and Fl for flagellum. The arrowhead indicates the junction between Pd and Fl. Red and blue arrows indicate the orientation of the joint axes of the head-scape joint (HS) and scape-pedicel joint (SP), respectively. Shaded sectors and round arrows indicate the slanted planes of motion of the scape (red) and pedicel*

(blue). See insert for a schematic frontal view. Right: Antennal working range during active searching behavior of a walking stick insect. Red and blue grid lines show 10° steps in joint angles of the left HS and SP joints, respectively. The underlying heat map shows the likelihood of the antenna to pass through a given sector of the spherical grid, with darker colors indicating higher likelihood. The head-fixed reference coordinate system is indicated by (x, y, z)

$$T(\mathbf{v}) = \begin{pmatrix} 1 & 0 & 0 & v_x \\ 0 & 1 & 0 & v_y \\ 0 & 0 & 1 & v_z \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

Note that each joint axis orientation vector, $\mathbf{r}$, may be significantly slanted with respect to the head-fixed reference coordinate system (e.g., in Fig. 1). The direction of $\mathbf{r}$ determines how the rotation direction of $\mathbf{R}(\varphi, \mathbf{r})$ corresponds to the sign of the angle φ . This is because rotation angles obey the right-hand rule: if the thumb of the right

hand is aligned with $\mathbf{r}$, then the flexed fingers of the same hand indicate the direction of positive φ .

As the SP joint always has a single DoF only, the right three matrices of the direct kinematics equation are the same for all insect species. Additional DoF of the HS joint can be added by multiplying an additional $\mathbf{R}(\varphi, \mathbf{r})$ for each DoF. For example, for a ball-and-socket HS joint with 3 DoF (e.g., of a honey bee), the direct kinematics equation reads

$$p(\psi, \theta, \phi, \beta) = \mathbf{R}(\psi, \mathbf{x})\mathbf{R}(\theta, \mathbf{y})\mathbf{R}(\phi, \mathbf{z})\mathbf{T}(\mathbf{p}_{\text{SP}})\mathbf{R}(\beta, \mathbf{r}_{\text{SP}})\mathbf{T}(\mathbf{p}_{\text{rest}})(0, 0, 0, 1)^T,$$

where $\mathbf{x}$, $\mathbf{y}$, and $\mathbf{z}$ are the unit vectors of the reference coordinate system and ψ , θ , and ϕ are

the *roll*, *pitch*, and *yaw* rotation angles about these axes.

Tactile Sensing in Insects, Fig. 2 *Top:* Schematic of the wall-following paradigm for tactual course control in running cockroaches. The bent antenna (blue) maintains contact to the wall and transmits information about the lateral distance, d , which depends on the contact distance, l , and velocity, v . Based on the estimated value of d , the nervous

system (green) has to adjust the net polar moment u at the point of rotation (red). *Bottom:* Block diagram of the control model proposed by Cowan et al. 2006, where the neural PD controller (green) adjusts u , thus affecting the body mechanics (red) and, in turn, the lateral contact distance experienced by the tactile sensor (blue)

Tactually Mediated Course Control During Running

A nice example for tactually mediated course control in locomotion is the wall-following paradigm in cockroaches, in which a running cockroach maintains a constant distance to a wall by use of information from antennal mechanoreceptors (Camhi and Johnson 1999). Figure 2 sketches an experiment by Cowan et al. (2006), in which a cockroach is following a straight wall until a corner, where the antenna senses a change in body-to-wall distance and causes the body to turn away from the wall. Assuming the simple case where the velocity heading of the animal's point of rotation coincides with the body orientation angle, the change of the lateral distance to the wall, d , depends on the contact distance, l , the velocity, v , and the body orientation angle θ according to $\dot{d} \approx l\dot{\theta} + v\theta$ (see Fig. 2, top). The control of the body orientation can be modeled by a Proportional-Derivative controller (PD controller) that adjusts the net polar moment, u , according to both the sensed distance to the wall, d , and the sensed rate of approach, $\dot{d}$, with $u = K_P(d - d_{Set}) + K_D\dot{d}$,

where K_P and K_D are the gains of the proportional and the derivative term of the difference between d and its set value, d_{Set} (Fig. 2, bottom). This moment is then filtered by the rotational dynamics of the body according to $u = J\ddot{\theta} + B\dot{\theta}$, where J is the polar moment of inertia, and B is a damping coefficient. The free parameters of this model may be estimated from stride-to-stride changes in kinematic measures from motion capture, using non-linear regression analysis (for details, see Cowan et al. 2006).

Target Selection vs. Response Selection

Robert McPeck

Biological and Vision Sciences, SUNY College of Optometry, State University of New York, New York, NY, USA

Definition

Target selection refers to the process of selecting a single object from a field of multiple objects as the goal of a movement. It can also be used to refer to the deployment of covert attention to a selected object, even when an overt movement is not

ultimately made. For overt actions, target selection specifies the movement goal (or end point), but not necessarily the effector that will be used or the trajectory that will be taken to reach the goal. In contrast, response selection is the process of choosing the appropriate action to take in response to a given stimulus. It is the intermediate process occurring between discrimination of a stimulus and planning of an action and usually involves a learned stimulus-to-response (S-R) mapping. For example, when driving a car toward an intersection, the usual response to a red traffic light (stimulus) is to press the brake pedal in order to stop the car (response).

Detailed Description

Target Selection

Natural environments are often complex and crowded with many different objects. Thus, the production of accurate goal-directed actions requires the selection of a single movement target and suppression of competing potential targets. A similar selection process is thought to underlie our ability to covertly shift attention to a target object of interest while ignoring distracting objects. Target selection is often modeled as a competition among potential targets occurring on a hypothetical “priority map” (e.g., Koch and Ullman 1985; Wolfe 1994; Itti and Koch 2001; Zelinsky 2008). The level of activation in the priority map associated with each potential target is dependent upon both top-down factors (such as the behavioral relevance of the target) and bottom-up factors (such as perceptual salience). In models where bottom-up factors are used exclusively, the priority map is often called a “saliency map.” Target selection occurs when the object with the highest level of activation in the map is selected and distracting objects are suppressed.

Much of the empirical research on target selection has focused on eye movements or arm-reaching movements. Based on physiological evidence, there does not appear to be a single priority map in the brain that is used for target selection. Rather, neural activity with the properties expected of a priority map can be found in several different regions of the brain, including areas in

the frontal and parietal cortices (e.g., the frontal eye field (Schall and Thompson 1999) and the lateral intraparietal area (Bisley and Goldberg 2010) for eye movements and the dorsal premotor area (Cisek and Kalaska 2010) and parietal reach region (Scherberger and Andersen 2007) for reaching movements). Subcortical areas involved in target selection include the basal ganglia (Shires et al. 2010), superior colliculus (McPeck and Keller 2004; Song et al. 2011; Krauzlis et al. 2013), and pulvinar (Wilke et al. 2010). It is largely unknown how target selection-related activity is coordinated across these different areas.

Response Selection

While target selection implies the spatial selection of a target, response selection describes a more abstract process: specifically, the linkage between a percept and a motor response. This link is usually described in terms of a stimulus-to-response (S-R) mapping, which indicates the appropriate response to make given a particular stimulus. The difficulty of response selection is dependent upon both the number of S-R pairs in the mapping (Hick 1952) and the compatibility of the mapping itself (Fitts and Seeger 1953; Kornblum et al. 1990). For example, in a task in which subjects are presented with four vertical lines in a row and told to press one of four buttons to indicate which line is the shortest, response selection is easier when the relative location of the correct response button corresponds to the location of the line (compatible S-R mapping) than if the arrangement of response buttons is shuffled relative to the positions of the lines to which they correspond (incompatible S-R mapping).

In many situations (especially those involving incompatible S-R mappings), it is difficult or impossible for subjects to perform response selection using more than one S-R mapping at a time, even when the two mappings involve different sensory modalities and different response effectors. This has led to the suggestion that response selection is a significant processing bottleneck for

humans (Pashler 1994). Neural activity related to response selection can be found across a network of brain areas, including the prefrontal, premotor, cingulate, and parietal cortices (Bunge et al. 2002; Schumacher and Jiang 2003; Rushworth et al. 2004; Hoshi and Tanji 2007).

Definition

Tempotron learning is an online gradient-based supervised learning rule for spiking neuron models that implement a binary classification of multi-neuronal spike patterns. A neuronal classifier whose synaptic efficacies are controlled by the tempotron learning rule is referred to as tempotron. The tempotron implements a binary decision rule: A spike pattern is classified as *target* pattern if the tempotron fires at least one output spike in response to the pattern. If the neuron remains silent, the pattern is classified as *null* pattern. The tempotron is trained on a training set consisting of labeled target and null patterns. When the tempotron misclassifies an input pattern during training, i.e., when its output does not match the desired response specified by the label, the tempotron learning rule adjusts each of the neuron's synaptic efficacies according to its contribution to the maximal postsynaptic membrane potential: increasing it when the desired response is to fire at least one spike and decreasing it if the correct response is to remain silent.

Detailed Description

Architecture and Task

The tempotron (Gütig and Sompolsky 2006) refers to a deterministic spiking neuron model with N synaptic afferents whose synaptic efficacies ω_i with $i = 1, \dots, N$ are governed by the tempotron learning rule. In the below treatment, the scalar efficacy ω_i refers to amplitude of the

postsynaptic potential (PSP) that is elicited by a single spike of the i th afferent, but more complex synapse models are possible. The task of the tempotron is to implement a binary classification of set of input spike patterns, each of which is labeled either as target or as null pattern. A correct classification requires the neuron to fire at least one spike in response to input patterns from the target class and to remain silent in response to input patterns from the null class.

Learning Rule

The tempotron learning rule solves the temporal credit assignment problem underlying the task of changing a neuron's response from not firing to firing. Since the tempotron classification task does not specify or constrain at what time an output spike in response to a target pattern should occur, the learning rule must choose an appropriate time and credit the neuron's synaptic efficacies accordingly. Tempotron learning uses the maximum postsynaptic potential $V_{\max}$ as objective function such that synaptic efficacies are modified along the gradient

$$\Delta\omega_i \propto \frac{\partial V_{\max}}{\partial \omega_i} = \frac{\partial V(t)}{\partial \omega_i} \Big|_{t=t_{\max}} \quad (1)$$

after each error trial. Each synaptic efficacy is changed according to its contribution to the postsynaptic membrane potential at the time $t_{\max}$ of the maximal postsynaptic depolarization. When the tempotron fails to fire in response to a target pattern, synaptic updates can be obtained by straightforward application of the above rule. However, when erroneous spikes are elicited by null patterns, a direct application of the above rule would require the evaluation of the subthreshold postsynaptic membrane potential without reset. Because it is unclear whether and if so how a neuron could gain access to this quantity, $V(t)$ in the original tempotron model (Gütig and Sompolinsky 2006) was replaced by a "shunted" voltage trace, which ignores all input spikes that arrive after the first action potential is fired.

Implementations

Tempotron learning has been implemented with current- (Gütig et al. 2013; Gütig and

Sompolinsky 2006) and conductance-based (Gütig and Sompolinsky 2009) leaky integrate-and-fire (LIF) neuron models. In the current-based LIF, the subthreshold membrane potential can be written as linear sum of PSPs, i.e.,

$$V(t) = \sum_{i=1}^N \omega_i \sum_{t_i^j < t} K(t - t_i^j) + V_{\text{rest}}, \quad (2)$$

where t_i^j denote the spike times of the i th afferent. The kernel

$$K(t - t_i^j) = V_0 \left(\exp \left[-\left(t - t_i^j \right) / \tau_m \right] - \exp \left[-\left(t - t_i^j \right) / \tau_s \right] \right)$$

is the normalized PSP contributed by each incoming spike with τ_m denoting the membrane integration time constant and τ_s denoting time constant of the exponentially decaying synaptic currents. The factor V_0 normalizes PSP kernels to 1 such that unitary PSP amplitudes are given by ω_i . The filter $K(t - t_i)$ is causal and vanishes for $t_i > t$. When $V(t)$ crosses the firing threshold at 1, the neuron fires a spike, and the voltage undergoes a smooth reset to V_{rest} by shunting all incoming spikes that arrive after the output spike (Gütig and Sompolinsky 2006).

Evaluation of the gradient (Eq. 1) for the voltage kinetics of the current-based LIF (Eq. 2) results in the synaptic update rule:

$$\Delta\omega_i = \pm \lambda \sum_{t_i^j < t_{\max}} K(t_{\max} - t_i^j)$$

where the plus sign refers to increases in synaptic efficacies when the tempotron failed to fire in response to a target pattern and the minus sign to a reduction of the weights when an erroneous spike was fired in response to a null pattern. The learning rate λ controls the overall scale of the synaptic updates.

Note that in the conductance-based LIF, the tempotron update rule is substantially more complex. This is due to the global coupling of input spikes through their contribution to the total postsynaptic conductance, which modulates the

effective integration time constant of the postsynaptic compartment (Gütig and Sompolinsky 2009).

Applications

Tempotron learning has been applied to a number of diverse neural classification tasks. Together, these applications have demonstrated the high capacity of simple neural architectures to read out a broad range of spike-timing-based neural representations including spike latency and temporal correlation codes (Gütig and Sompolinsky 2006). In an application to electrophysiologically recorded spike trains, the tempotron has been successfully used to decode visual stimulus information encoded by the relative spike latencies of retinal ganglion cell population activity (Gütig et al. 2013). In an application to auditory processing, a conductance-based implementation of the tempotron has been shown to be capable of subserving time-warp-invariant information processing (Gütig and Sompolinsky 2009). The storage capacity of the tempotron and the structure of its solution space have been studied analytically in Rubin et al. (2010).

Context

A growing number of electrophysiological studies in the 1990s and 2000s have described instances of neural information processing in central nervous pathways, where sensory information is encoded by the precise relative timing of action potentials within multi-neuronal spiking activity (VanRullen et al. 2005). During the same period, synaptic physiologists have uncovered novel rules of synaptic plasticity in which the precise timing of presynaptic and postsynaptic action potentials influences changes in synaptic efficacies (Feldman 2012). The tempotron has been developed to answer the question whether and if so how neurons can learn to decode spike-timing-based neural representations. In a parallel line of research, computational neuroscientists have also asked to what degree neuronal architectures are capable of encoding information in precise sequences of output spikes (Gütig 2014; Pfister et al. 2006; Ponulak and Kasinski 2010; Xu et al. 2013).

Definition

The Virtual Brain (TVB) (TVB main site <https://www.thevirtualbrain.org/>) ecosystem offers a simulation environment for Large-Scale Brain Networks: by manipulating network parameters, in particular the brain's structural connectivity,

The Virtual Brain simulates a whole brain behavior as it is commonly observed in clinical scanners (e.g., EEG, MEG, fMRI).

Though The Virtual Brain incorporates the complex world of neuro-chemistry only to a small degree, it gains a lot by not becoming as complex as the brain itself. Instead, The Virtual Brain embraces and extends concepts from computational, cognitive, and clinical neuroscience in order to drastically reduce the model’s complexity while still keeping it sufficiently realistic and delivering the same output as clinical brain-scanners.

Recent efforts are now linking TVB’s large scale modeling approach with other scales in brain simulation.

Detailed Description

Application

We started developing TVB with one main objective in mind: to be useful for a large variety of computational neuroscience research and clinical efforts by enhancing accessibility, performance, and understanding of primary and auxiliary modeling tools. This translated into the software being open-source (TVB source code repositories: <https://github.com/the-virtual-brain>) (under GPLv3), available on all major operating systems, and having both a web graphical user interface (for fast access to features and an easy learning curve) but also a command line interface for fine tuning by experts (Table 1).

Packages

TVB’s code base is modular, resulting in multiple packages to release and distribute. The principal packages are as follows:

- tvb-library (<https://pypi.org/project/tvb-library/>) is our most critical package, holding the simulator code. It can be used by itself through command line access in a Python environment.
- tvb-framework (<https://pypi.org/project/tvb-framework/>) depends on tvb-library, and adds

The Virtual Brain (TVB): Simulation Environment for Large-Scale Brain Networks, Table 1 Technical stack for TVB ecosystem: supports all major operating systems, it is Python based (only version 3 supported as of 2020), with many 3rd party dependencies, a rich project management set of tools (Jira) and extensive documentation (Sphinx, Confluence, Wiki)

TVB technical features	
License	GPL v3
Citation	Sanz Leon & others (2013) The Virtual Brain: a simulator of primate brain network dynamics <i>Frontiers in Neuroinformatics</i> 7:10. https://doi.org/10.3389/fninf.2013.00010
Supported OS	Windows, Mac, Linux
Access	Console (Command Line API) and Web GUI
Main Prog. Language	Python (version 3)
Main 3rd party dependencies	Numpy, Scipy, Numba, CherryPy, WebGL, HDF5

- storage functionality (HDF5 and PostgreSQL DB) as well as a web graphical interface.
- TVB-gdist (<https://pypi.org/project/tvb-gdist/>) is a small C++ module used for computing geodesic distances on a surface (like the cortical waved surface) for the Local Connectivity calculus in TVB. tvb-gdist is an optional dependency for tvb-library (as long as surface simulations are not necessary to be launched).
 - tvb-data (Zenodo <https://zenodo.org/record/3688773#.XwCPUJMzaL8>) is a collection of demo data compatible with TVB software. It can be used for quickly testing our functionality. Personal datasets are usually preferred when working with TVB (Fig. 1).

TVB’s main packages are stable, in terms of software maturity, having had regular publicly releases since 2012. Since then, we have constantly added new features and fix bugs in these packages, but the API mostly remains unchanged,

unless signaled by the version number change (e.g., from version 1.5.* to 2.0).

Under the TVB umbrella, we developed an ecosystem of packages that communicate through APIs and serve various use-cases (e.g., The Virtual Epileptic Patient, data preprocessing); thus, the main packages are not the only ones we maintain and distribute. Part of this ecosystem can be observed in Fig. 2.

The Virtual Brain (TVB): Simulation Environment for Large-Scale Brain Networks, Fig. 1 TVB main packages and their direct relations. Packages with a RED border are the main ones. Packages in BLUE are optional. S-User access TVB through scripting or command line access. G-User access TVB through a graphical user interface (web based)

Architecture of tvb-Library

tvb-library package holds the code for our main feature: the simulator, which will be represented by a Simulator class, capable of receiving all input parameters configurable by the users, loop over time steps, and return at each step the numeric results (as TimeSeries steps) (Fig. 3).

The Simulator class will work with generic Large Scale Connectivity (often referred to as the Connectome), Neuronal Mass Models, generic Integrators, Coupling Methods (between simulated regions), and generic Monitors (for integrating the results). This is implemented in Python through inheritance, and then at runtime, we polymorphically use the right differential equation, integration method, etc., based on the current configuration given by the user. This makes our simulator flexible and easy to extend

The Virtual Brain (TVB): Simulation Environment for Large-Scale Brain Networks, Fig. 2 Part of TVB ecosystem with our main packages from Fig. 1 (collapsed under the red shape) plus adjacent other packages

The Virtual Brain (TVB): Simulation Environment for Large-Scale Brain Networks, Fig. 3 TVB simulator main components. (Sanz Leon & others (2013) *The Virtual Brain: a simulator of primate brain network dynamics* *Frontiers in Neuroinformatics* 7:10. <https://doi.org/10.3389/fninf.2013.00010>)

The Virtual Brain (TVB): Simulation Environment for Large-Scale Brain Networks, Fig. 4 TVB data model – classes diagram

(e.g., by adding new Model classes) without losing too much in performance or simplicity.

Next to the simulator, still part of *tvb-library*, we also keep our base data model. It consists again of a series of Python classes, with various relations between them (inheritance, aggregation, association). They all inherit from `HasTraits` base class, and they annotate each of their fields with at least a type, plus short documentation and optionally an accepted range interval (useful especially if we are to run parameter space explorations) (Fig. 4).

Architecture of *tvb-Framework*

tvb-framework contains several extra features for the TVB ecosystem: a data storage, a small flow

orchestrator for running multiple operation types, a web GUI, a REST API.

tvb-framework depends on *tvb-library*, both for the simulation operation, but also for its data types, which will be central into our orchestrations as we want to have it data-oriented: `DataTypes` are the most important resource in TVB, stored in (possibly very large) HDF5 files, and indexed in a relational DB (Fig. 5).

tvb-framework introduces an important grouping entity named **Project**, which is left flexible at the user’s need of what it represents (one single subject, one group case-study, one patient recording, etc.) but it is the central piece used when sharing data: everything under a project can be shared with colleagues using the same TVB installation (Fig. 6).

The Virtual Brain (TVB): Simulation Environment for Large-Scale Brain Networks, Fig. 5 Data oriented architecture. Each TVB operation can get DataTypes as input and can produce other DataTypes

TVB Web GUI can be installed either on a local machine (then used by a single user) or on a shared server or cloud environment, and then someone will assume the role of administrator, and others can manage their own Projects in this installation, without being able to see the other's work, unless explicitly shared by the Project creator (Fig. 7).

tvb-framework uses a relational database with indexed metadata for quick access. For example, when we want to check if a compatible Surface and RegionMapping exists in the current Project for using it with the current Structural Connectivity for launching a surface based simulation, the PostgreSQL DB responds very fast with an answer. Also, we use the shared relational DB together with a shared file storage, as synchronization point, when Operations are launched in a distributed manner from TVB (cloud or cluster installations).

Example Code

Coding with TVB requires Python knowledge. One would start by preparing a Simulator instance and changing the defaults as necessary. Full example code: https://github.com/the-virtual-brain/tvb-root/blob/master/framework_tvb/tvb/interfaces/command/demos/operations/run_simulation.py:

```
simulator = Simulator()
simulator.connectivity = my_c
simulator.coupling = Scaling()
simulator.simulation_length = 100
```

Then, instantiate a SimulatorService and launch the configured simulation as a framework operation:

```
service = SimulatorService()
operation = service.
async_launch_and_prepare_simulation
    (BurstConfiguration(proj.id),
    proj.administrator, proj,
    algo, simulator)
```

The Virtual Brain (TVB): Simulation Environment for Large-Scale Brain Networks, Fig. 6 TVB flow models inside tvb-framework

The Virtual Brain (TVB): Simulation Environment for Large-Scale Brain Networks, Fig. 7 Sequence diagram for running an operation with TVB-framework

The Virtual Brain (TVB): Simulation Environment for Large-Scale Brain Networks, Fig. 8 TVB downloads number evolution since 2012 (when the first release happened) until the end of June 2020. The blue line counts downloads of TVB_Distribution (ready to use package). The green dotted line adds the Pypi downloads for tvb-library also (not counted before June 2019)

Now, it only remains to wait for the operation to finish and to collect the result:

```
while not operation.has_finished:
    sleep(5)
operation = get_operation_by_id(
    operation.id)
if operation.status == FINISHED:
    ts = dao.get_generic_entity(
        TimeSeriesRegionIndex,
        operation.id,
        "fk_from_operation")[0]
```

History

In October 2010, Viktor Jirsa, Randy McIntosh, Jochen Mersmann, and Lia Domide convened in Marseille, France, and drafted the first architecture of TVB in the foundational TVB white paper (TVB White Paper in its raw form: https://github.com/the-virtual-brain/tvb-root/tree/master/tvb_documentation/manuals/DeveloperReference). With the addition of Petra Ritter as applications coordinator, the TVB team advanced rapidly resulting in the first public release version 1.0 in November 2012. Since then the code base has evolved steadily with major contributions made by Stuart Knock, Marmaduke Woodman, Paula Sanz-Leon, Paula Popa, Mihai Andrei, and many others. In 2020 TVB has over 30,000 recorded downloads. TVB is today a product with a lifespan spreading over multiple projects (often equivalent to funded grants), notably the European IT flagship Human Brain Project (Human Brain Project: <https://www.humanbrainproject.eu/en/>) (Fig. 8).

Since 2014 TVB participates with proposed projects and mentors in the Google Summer of Code program (<https://summerofcode.withgoogle.com/>), under the INCF umbrella, thus giving students around the world the chance to contribute and learn interesting things about neuroscience in a real project. The original TVB reference is Sanz-Leon et al (2013). Integration of neuroinformatics tools for TVB are provided in Ritter et al (2013) and Woodman et al (2014). TVB theory is elaborated in Sanz-Leon et al (2015). All other references provide applications of TVB in diverse domains including basic and clinical neuroscience.

Thermodynamic Models of Ion Channels

Alain Destexhe

Unit of Neuroscience Information and Complexity (UNIC), Paris-Saclay University, Institute of Neuroscience (NeuroPSI), Centre National de la Recherche Scientifique (CNRS), Gif-sur-Yvette, France

Definition

Thermodynamic models provide a kinetic description of ion channels starting from first principles. Instead of using empirical functions for the voltage dependence of the parameters of the ion channel, they are deduced from a physically plausible framework. This framework formalizes the effect

of the interaction between the electric field and the ion channel. This interaction can be linear or non-linear, leading to different classes of models for voltage-dependent ion channels.

Detailed Description

Introduction

The first quantitative description of the voltage dependence of ionic currents and their role in generating action potentials was provided by Hodgkin and Huxley (1952). This description, however, was semiempirical. They postulated that the ionic conductance was dependent on the assembly of “gating particles,” acting independently and in a voltage-dependent manner. This formalism gave rise to the well-known Hodgkin-Huxley set of equations, which could account quantitatively for the genesis of action potentials in squid giant axon. However, the voltage dependence of the rate constants in the model was fit to voltage-clamp measurements using empirical functions of voltage.

Instead of using empirical functions, it is also possible to deduce the functional form of the voltage dependence of the rate constants from thermodynamics and in particular from the effect of the electric field on the free energy of the transition between conformational states of the channel. These *thermodynamic models* (Eyring et al. 1949; Tsien and Noble 1969; Hill and Chen 1972; Stevens 1978; Hille 2001) provide a firm physical basis to constrain and parameterize the voltage dependence of rate constants, which are then used to fit voltage-clamp data.

In this chapter, we review these thermodynamic models of ion channels by contrasting two types of models. We first review the *linear thermodynamic models*, which assume that the effect of the electric field is linear on the free energy, which results in simple exponential dependences of transition rates. Second, we review *nonlinear thermodynamic models* (Destexhe and Huguenard 2000), where the effect of the electric field on the free energy can be nonlinear, capturing more realistic effects that can be fundamental for ion channel function.

Thermodynamic Models

Thermodynamic models explore the possibility of deducing the exact functional form of the voltage dependence of the model from thermodynamics. This type of model assumes that the gating of ion channels operates through successive conformational changes of the ion channel protein. Consider an elementary transition between an initial (I) and a final (F) state, with a rate constant $r(V)$ that is voltage dependent:

According to the theory of reaction rates (Eyring 1935; Johnson et al. 1974), the rate of the transition depends exponentially on the free energy barrier between the two states:

$$r(V) = r_0 e^{-\Delta G(V)/RT}, \quad (2)$$

where r_0 is a constant and $\Delta G(V)$ is the free energy barrier, which can be written as

$$\Delta G(V) = G^*(V) - G_0(V) \quad (3)$$

where $G^*(V)$ is the free energy of an intermediate state (activated complex) and $G_0(V)$ is the free energy of the initial state. The relative values of the free energy of the initial and final states (G_0 and G_1) determine the equilibrium distribution between these states, while the kinetics of the transition depend on the size of the free energy barrier $\Delta G(V)$.

Linear Thermodynamic Models It is usually assumed that a linear voltage dependence of the free energy is sufficient to describe the gating of ion channels (Tsien and Noble 1969; Stevens 1978; Borg-Graham 1991; Andersen and Koeppe 1992; Hille 2001). According to these “linear thermodynamic models,” the free energy of a given state i can be written as

$$G_i(V) = A_i + B_i V \quad (4)$$

where the constant A_i corresponds to the free energy that is independent of the electrical field and the linear term $B_i V$ to the effect of the electrical

field on isolated charges and rigid dipoles (Hill and Chen 1972; Stevens 1978; Andersen and Koeppe 1992). For example, linear terms in V will result if the conformations differ in their net number of charges or if the conformational change is accompanied with the translation of a freely moving charge inside the structure of the channel.

Applying Eqs. 2, 3, and 4, the rate constant can be written as

$$r(V) = r_0 e^{-(a+bV)/RT}, \quad (5)$$

where $a = A^* - A_0$ and $b = B^* - B_0$ represent differences between the constant and linear components of the free energy of the initial and activated states (according to Eq. 4).

Consider the particular case of a reversible open-closed transition

where C and O are, respectively, the closed and open states and α and β are the forward and backward rate constants. Applying Eq. 5 to forward and backward reactions leads to the following expression for the voltage dependence of rate constants:

$$\begin{aligned} \alpha(V) &= \alpha_0 e^{-(a_1+b_1V)/RT} \\ \beta(V) &= \beta_0 e^{-(a_2+b_2V)/RT} \end{aligned} \quad (7)$$

where a_1 , a_2 , b_1 , and b_2 are constants specific for this transition. In the following, this form with simple exponential voltage dependence of rate constants will be called *linear thermodynamic model*.

A further simplification is to consider that the conformational change consists of the movement of a freely moving gating particle with charge q (Hodgkin and Huxley 1952; see also Borg-Graham 1991). The forward and backward rate constants can be written as

$$\begin{aligned} \alpha(V) &= A e^{-\gamma q F(V-V_H)/RT} \\ \beta(V) &= A e^{(1-\gamma) q F(V-V_H)/RT}, \end{aligned} \quad (8)$$

where γ is the relative position of the energy barrier in the membrane (between 0 and 1), V_H is the half-activation voltage, and A is a fixed constant. This form was introduced by Borg-Graham (1991) to parameterize Hodgkin-Huxley models. Its parameters are very convenient for fitting experimental data: V_H and q affect the steady-state activation/inactivation curves, whereas A and γ only affect the time constant with no effect on steady-state relations.

Nonlinear Thermodynamic Models Although linear thermodynamic models have proved to be accurate for many purposes (reviewed in Hille 2001), their major drawback is that the time constants can reach arbitrarily small values, which may lead to aberrant behavior. In reality, the complex molecular structure of ion channels imposes bounds on their transition rates. Because exponential functions of voltage cannot account for rate-limited transitions, this problem is usually solved by introducing an artificial minimal rate (Borg-Graham 1991), forcing the rate constants to saturate (Willms et al. 1999) or using additional voltage-independent rate-limiting transitions. These procedures are, however, largely empirical, which contradicts with the initial aim of physical plausibility of thermodynamic models.

Nonlinear thermodynamic models (Destexhe and Huguenard 2000) were proposed as a physically plausible framework to solve this problem. These models are based on a functional form for the voltage dependence of rate constants that takes into account more realistic effect of the electrical

field on the ion channel protein. This functional form naturally accounts for rate-limiting effects, and its applicability was illustrated by modeling the complex voltage dependence of T-type calcium currents (Destexhe and Huguenard 2000, 2010).

In general, the effect of the electrical field on a protein will depend on the number and position of its charged amino acids, which will result in both linear and nonlinear components in the free energy. Without assumptions about the underlying molecular structure, the free energy of a given state i can be written as a Taylor series expansion of the form

$$G_i(V) = A_i + B_i V + C_i V^2 + \dots \quad (9)$$

where A_i corresponds to the free energy that is independent of the electrical field, the linear term $B_i V$ to the interaction between electrical field with isolated charges and rigid dipoles, as described above. The higher-order terms describe effects such as electronic polarization and pressure induced by V (Hill and Chen 1972; Stevens 1978; Andersen and Koeppe 1992), as well as mechanical constraints (see below).

In general, each conformational state of the ion channel protein will be associated with a given distribution of charges and will therefore be characterized by a given set of coefficients in Eq. 9. This is also true for the activated state, which is a particular case of conformation. Applying Eqs. 2 and 9, the rate constant can be written more generally as

$$\begin{aligned} r(V) &= r_0 e - [(A^* + B^* V + C^* V^2 + \dots) - (A_0 + B_0 V + C_0 V^2 + \dots)] / RT \\ &= r_0 e - (a + bV + cV^2 + \dots) / RT, \end{aligned} \quad (10)$$

where $a = A^* - A_0$, $b = B^* - B_0$, $c = C^* - C_0$, ... represent differences between the linear and nonlinear components of the free energy of the initial and activated states (according to Eq. 9).

Applying these considerations to the reversible open-closed transition (Eq. 6) leads to the following general expression for the voltage dependence of rate constants:

$$\begin{aligned}\alpha(V) &= \alpha_0 e - (a_1 + b_1 V + c_1 V^2 + \dots)/RT \\ \beta(V) &= \beta_0 e - (a_2 + b_2 V + c_2 V^2 + \dots)/RT\end{aligned}\quad (11)$$

where $a_1, a_2, b_1, b_2, c_1, c_2, \dots$ are constants specific of this transition.

It is important to note that, in general, these parameters are not necessary interrelated because the three different conformations implicated here (initial, activated, final) may have very different distributions of charges, resulting in different coefficients in Eq. 9 and thus also resulting in different values for $a_1 \dots c_2$. In the following, this general functional form for the voltage dependence of rate constants will be called *nonlinear thermodynamic model*.

In the “low-field limit” (during relatively small transmembrane voltages), the contribution of the higher-order terms may be negligible, and one can approximate the free energy in various ways. The simplest approximation would only consider first-order terms in V , which gives the linear thermodynamic model (Eq. 7). Other approximations would consist in quadratic or higher-order expansions of the free energy. These approximations include nonlinear effects of the voltage on the free energy and may lead to saturating rate constants, as we will show below.

For example, the quadratic expansion of Eq. 11 can be written as

$$\begin{aligned}\alpha(V) &= Ae - [b_1(V - V_H) + c_1(V - V_H)^2]/RT \\ \beta(V) &= Ae [b_2(V - V_H) + c_2(V - V_H)^2]/RT,\end{aligned}\quad (12)$$

where $A, b_1 \dots c_2$ are constants as defined above.

In addition to the effect of voltage on isolated charges or rigid dipoles, described in Eq. 7, these forms account for more sophisticated effects such as electronic polarization or the deformation of the protein by the electrical field (Hill and Chen 1972; Stevens 1978). This contribution, however, was estimated to be small (see Sigworth 1993). Higher-order terms would also take into account the presence of mechanical constraints on the gating process (Destexhe and Huguenard 2000).

If gating results from the movement of a freely moving charge, the free energy will depend linearly on voltage. However, if gating depends on the movement of a gating charge subject to a mechanical constraint (which was modeled as a spring of constant k ; Destexhe and Huguenard 2000), the force due to this constraint will contribute for a nonlinear term in the free energy ($-k V^2$ in the case of a spring). This model is probably more realistic than using a freely moving charge, because charged residues in general are strongly constrained by the structure of the protein and are therefore not moving freely. Adding more complex constraints will likely result in adding further nonlinear contributions to the free energy.

Applications

Applications to Hodgkin-Huxley Models

As discussed above, an important caveat of linear thermodynamic models is that the time constants may be arbitrarily close to zero. This is due to the fact that rate constants described by simple exponentials of voltage (Eq. 7) can reach arbitrarily large values. Different solutions to this problem have been proposed (Borg-Graham 1991; Willms et al. 1999) and consisted in artificial alterations of the Hodgkin-Huxley formalism by either setting minimal values for the rate constants or forcing the rate constants to saturate at extreme voltages, but these alterations were largely empirical, which was inconsistent with the initial aim of thermodynamic models.

A physically plausible basis for more realistic voltage-dependent rates was proposed under the form of nonlinear thermodynamic models (Destexhe and Huguenard 2000). The basis of these models is that in reality, the rate of conformational changes of proteins is necessarily bounded by mechanical constraints, and consequently, the transition time constants have a minimum value. Nonlinear thermodynamic models have explored the hypothesis that this minimum value is due to nonlinear effects of the voltage on the ion channel. Such models have examined functional forms for the voltage dependence of rate constants which include effects such as

deformation of the protein by the electric field (Hill and Chen 1972; Stevens 1978; Andersen and Koeppel 1992) or mechanical constraints on the gating process (Destexhe and Huguenard 2000). These considerations lead to a more general form of the voltage dependence of the free energy. The resulting model can capture the saturation of the rate constants at some voltages and naturally leads to time constants saturating to a minimal value. (In addition to be more realistic, models with a minimal time constant are also more stable numerically.) This type of model were shown to capture experimental data showing such a minimal time constant, as illustrated for the T-type calcium current (Destexhe and Huguenard 2000).

It must however be kept in mind that models in which the free energy is represented by a quadratic or third-order polynomial of V are approximations. In its non-approximated form (Eq. 9), the free energy can be expressed as an infinite-order polynomial of V (Stevens 1978). Approximating this form by a second or third-order polynomial relies on the hypothesis that the voltage is not too large (the “low-field limit”). Consequently, these forms are only adequate for describing the behavior of the channel in a specific range of membrane potential.

Applications to Markov Models

The nonlinear thermodynamic formalism is not specifically related to the Hodgkin-Huxley model but is also applicable to any type of voltage-dependent model, including Markov representations. For example, when macroscopic voltage-clamp data reveal that the time constants saturate to a minimum value for activation, it is usually assumed (e.g., Chen and Hess 1990) that this behavior requires two successive transitions:

where C_1 and C_2 are two distinct closed states of the gate and the rate constants α and β are simple exponentials of voltage (Eq. 7). Because the second transition is not dependent of voltage, it will act as a rate-limiting factor when α and β reach

high values. In this case, the system will be governed essentially by k_1 and k_2 , which impose a limit on the rate of activation/inactivation.

Although this scheme may be more realistic, it is still unrealistic that the simple exponential representation for α and β permits the first transition to occur arbitrarily fast at some voltages. This problem can be solved by using nonlinear thermodynamic models for α and β , leading to a simpler scheme with only one transition:

Here, the rate constants $\tilde{\alpha}$ and $\tilde{\beta}$ are rate constants described by nonlinear thermodynamic models (Eq. 11). Thus, in this case, the minimum value of the time constant is not interpreted as due to the existence of a rate-limiting transition, but due to mechanical constraints in the effect of the electrical field on the protein. Nonlinear thermodynamic models therefore open the possibility of describing the gating of ion channels using more compact models with few states, which may be of great value to obtain physically plausible models.

Definition

Theta-neuron is a one-dimensional neural model that describes the state of the neuron with a phase variable:

$$\theta' = (1 - \cos \theta) + (1 + \cos \theta) \times (\beta + \text{Inputs}(t)) \quad (1)$$

where θ is between 0 and 2π , β is a constant parameter, and $\text{Inputs}(t)$ summarize the time-dependent inputs to the model.

Theta-neuron is equivalent to the quadratic integrate-and-fire (QIF) neuron or the quadratic normal form for the SNIC bifurcation, making the theta-neuron a canonical neural model: in a sense all models exhibiting the SNIC bifurcation can be reduced (in a sufficiently local neighborhood of the bifurcation) to the theta-neuron.

Detailed Description

The theta-neuron, also known as the Ermentrout-Kopell canonical model, was first derived in Ermentrout and Kopell (1986) to study bursting activity in coupled networks. While the initial intent of this model was to model neuronal oscillators, subsequent works used the theta-neuron as a general neuronal model for both the oscillatory regime (above the bifurcation) and the excitable regime (below the bifurcation).

The theta-neuron is equivalent to the quadratic integrate-and-fire neuron, as it is derived by a change of variables from the quadratic normal form for the SNIC bifurcation.

Let us start with a dynamical equation that describes the dynamics of a system near a SNIC bifurcation. It can be shown that any system of arbitrary dimension admitting a SNIC can be described by a canonical equation on $R(1)$:

$$x'(t) = x^2(t) + \beta \quad (2)$$

Here β determines if we have two steady states or if the solutions blow up in real time periodically. When $\beta < 0$, the two states are stable and unstable points (given by $x = -\sqrt{\beta}$; $x = \sqrt{\beta}$ respectively). Note that in the full system the latter corresponds to a saddle point with a one-dimensional unstable manifold that is invariant. If $x(t)$ is perturbed beyond that upper steady state, the solution blows up in finite time. Note that this equation is a bit cumbersome as there are infinities involved. So we can wrap the solutions on a phase:

$$x(t) = \tan(\theta/2) \quad (3)$$

and then recall that

$$\begin{aligned} x'(t) &= \frac{d(\tan(\theta/2))}{dt} = \frac{1}{\cos^2(\theta/2)} \frac{1}{2} \theta' \\ &= x^2 + \beta \end{aligned} \quad (4)$$

or

$$\frac{1}{\cos^2(\theta/2)} \frac{1}{2} \theta' = \tan^2(\theta/2) + \beta \quad (5)$$

Now we use the half-angle formulas and we get:

$$\theta' = (1 - \cos \theta) + (1 + \cos \theta)(\beta) \quad (6)$$

Here, the solution is reset at $\theta = 0 = 2\pi$. The flow is slow around the fixed points and speeds up as θ nears π . This is exactly what happens in full models. We can define the spike to be in the neighborhood of $\theta = \pi$. Note that it is quite convenient since the discontinuity is not at the spike (as opposed to the integrate-and-fire family of neural models). The spike can be easily visualized by plotting $y(t) = (1 + \cos \theta)$ (Figs. 1 and 2).

When β is below zero, we have an excitable model (steady states: stable $\theta_{\text{unst}} = 2 \tan^{-1}(-\sqrt{\beta})$ and unstable $\theta_{\text{unst}} = 2 \tan^{-1}(\sqrt{\beta})$). When β is above zero, we

have a periodic solution (traversing from 0 to 2π). The period of these oscillations is proportional to $\sqrt{\beta}$. Note also that the excitability parameter β is now included multiplicatively, where the term $(1 - \cos \theta)$ corresponds to the infinitesimal phase-response curve of the model (see below).

This tells us how we can incorporate time-dependent inputs into the model:

$$\begin{aligned} \theta' &= (1 - \cos \theta) + (1 + \cos \theta) \\ &\times (\beta + \text{Inputs}(t)) \end{aligned} \quad (7)$$

We can easily write an equation for synaptic variables as inputs (as was done in Gutkin et al. 2001).

$$\begin{aligned} \theta' &= (1 - \cos \theta) + (1 + \cos \theta) \\ &\times \left(\beta + \sum g_{ij} s_{ij} \right) \end{aligned} \quad (8)$$

where g_{ij} is the synaptic weight (positive for excitatory, negative for inhibitory) and

$$s'_{ij}(t) = -\frac{s_{ij}}{\tau_s} + (1 - s_{ij})e^{-\rho(1 - \cos(\theta_r - \theta_{\text{thresh}}))} \quad (9)$$

Where ρ is roughly speaking the rise time of the synapse (in Gutkin et al. 2001, ρ is taken as 20 for AMPA-like synapses), θ_{thresh} is the threshold above which the synapse activates: it should

Theta Neuron Model, Fig. 1 Diagram of theta-neuron. Here we show the structure of the theta-neuron dynamics. *Left* diagram is for the theta-neuron on the excitable regime, where $\beta < 0$. Below the θ_{thresh} the phase θ converges to θ_{rest} . When perturbed above the threshold, the phase makes a procession past $\theta = \pi$ (note that π is at the top of the phase diagram). The flow is slow near the threshold and the rest and is fast near π , where the spike takes place. The reset of the phase θ is at $\theta = 0 = 2\pi$, which

not at all near the spike. Note that as β moves near zero, the two fixed points θ_{thresh} and θ_{rest} move closer to each other. *Center* diagram is right at the bifurcation where $\beta = 0$ and the two fixed points have coalesced to form a saddle-node complex: this is the saddle-node bifurcation. When β moves above zero, the fixed point disappears leaving a limit cycle. *Right* diagram: on this limit cycle the flow is slow near the former saddle-node (or its ghost) and still fast near π . This indeed looks like repetitive spiking

Theta Neuron Model, Fig. 2 Coupled theta-neurons. Example of two theta-neurons coupled with strong recurrent excitatory synapses of AMPA type. *Upper panel* shows the sustained activity in the pair; here we plot $y(t) = 1 + \cos\theta$ for the two neurons: blue and red. *Middle panel* shows an expanded end of the sustained episode, showing that it terminates because the two neurons are synchronized – the basic mechanism is the refractory period

inherent in the theta-neuron dynamics. *Third panel* shows the synaptic variables $s(t)$ that are triggered by the spiking. The *lower panel* shows the impact that each synapse has on the postsynaptic phase θ which we can call the synaptic efficacy $(1 + \cos\theta) * s(t) * g_s$; this is the synapse multiplied by the PRC. Note that for the synchronized spikes, the efficacy drops. (Modified from Gutkin et al. 2001)

be close to the spike or θ_{thresh} approx. π (in Gutkin et al. 2001 taken $\theta_{\text{thresh}} = 3$); τ_s is the synaptic decay time scale. A slightly different formula is given in Borghers and Kopell (2003).

One can also write down synaptic equations taking into account the synaptic reversal potentials (i.e., modeling the synapses as conductances). Following the derivation from Borghers

and Kopell (2003), let us say that in the QIF equation we have a synapse $g_s s(t)$ ($V - E_{\sin}$). Then we do the change of variables as above to get the theta-neuron (Fig. 2):

$$\theta' = (1 - \cos \theta) + (1 + \cos \theta) \times (\beta + K g_s s(t)) - g_s s(t) \sin \theta \quad (10)$$

where K is a constant dependent on the synaptic reversal potential E_{syn} . For example, in Borghers and Kopell (2008), $K = 12$ for the excitatory synapses and $K = -3/2$ for the inhibitory synapses.

Including the synapses allows for the theta-neuron to be used in circuits (e.g., Gutkin et al. 2001) and networks (e.g., see Borghers and Kopell 2003). Similar equations can be written down for gap junction coupling and for NMDA synapses.

Stochastic Theta-Neuron

We can also incorporate noise in the theta-neuron. Starting from the stochastic differential equation for the quadratic normal form:

$$dx = (x^2 + \beta)dt + \sigma dW_t \quad (11)$$

Here things are a little bit tricky as stochastic calculus implies an additional drift term (deterministic term) after the change of variables from $x(t)$ to $\theta(t)$:

$$d\theta = \left[(1 - \cos \theta) + (1 + \cos \theta) \left(\beta + I(t) + \frac{\sigma^2}{2} \sin \theta \right) \right] dt + \sigma(1 + \cos \theta) dW_t \quad (12)$$

This is the equation derived in Lindner et al. (2003) and reader can follow the arguments on converting Stratonovich to Ito interpretation in that paper.

Note that early use of the stochastic theta-neuron (Gutkin and Ermentrout 1998) tacitly presumed that the variance of the noise is small enough to ignore the σ^2 term giving

$$d\theta = [(1 - \cos \theta) + (1 + \cos \theta)(\beta + I(t))]dt + \sigma(1 + \cos \theta)dW_t \quad (13)$$

Adaptive Theta-Neuron

We can incorporate a slower adaptation current (or slower regenerative currents):

$$\theta' = (1 - \cos \theta) + (1 + \cos \theta)(\beta - \mu z) \quad (14)$$

$$\tau_z z' = D(\theta)(1 - z) - z \quad (15)$$

$$D(\theta) = \kappa \exp - C(1 - \cos(\theta - \theta_z)) \quad (16)$$

Here μ is the strength of the adaptation current, and the parameter θ_z controls if the adaptation current is voltage dependent (e.g., M current; with θ_z relatively low) or spike dependent (e.g., the AHP current; with θ_z close to π). This makes the adaptive theta-neuron analogous to the Izhikevich neuron (Izhikevich 2004). Parameters are as follows: τ_z is the adaptation time constant, on the order of 100 ms; κ and C are scaling parameters in the activation term D (in Gutkin et al. 2005 $\kappa = 8$, $C = 2$) (Fig. 3).

Some Properties, Dynamics, and Facts

The theta-neuron is a canonical model for class I excitability: its equivalent to the quadratic normal form for the saddle-node on an invariant cycle bifurcation (SNIC). Its FI curve is continuous, with zero onset frequency for the oscillatory response and period scaling as:

$$T_{\text{period}} = \frac{\pi}{\sqrt{\beta}} \quad (17)$$

Interestingly in the excitable regime, perturbing the phase above the upper unstable fixed point $\theta_{\text{unst}} = 2 \tan^{-1}(\sqrt{\beta})$, which acts as the spike-generating threshold, results in a spike; however, the delay to this spike in time can be arbitrarily long as the perturbation gets nearer to

Theta Neuron Model, Fig. 3 Adaptive theta-neuron. Dynamics of the adaptive theta-neuron. The *upper panel* shows the spiking with a characteristic adaptation of the firing rate. The *middle panel* shows the activation of the $z(t)$

parameterized to act as $I-M$ (muscarine-sensitive voltage-dependent K current). *Lower panel* shows the instantaneous firing frequency. (Modified from Gutkin et al. 2005)

the θ_{unst} . This points out an important property of the theta-neuron: spikes are really all-or-none events with a hard spiking threshold. However, the timing of the spikes evoked is “soft” as it depends exquisitely on the size of the peri-threshold stimulus. We can even calculate explicitly how the time to the spike depends on the size of the peri-threshold perturbation ϵ (meaning that we perturb $\theta \in$ above the threshold or $\theta(t=0) = \theta_{\text{unst}} + \epsilon$) as well as the excitability parameter β :

$$T_{\text{spike}} = \frac{-\tanh^{-1}\left(1 + \frac{\epsilon}{\sqrt{\beta}}\right)}{\sqrt{\beta}} \quad (18)$$

Note that this function blows up as ϵ goes to zero and also it gets “flatter” as β tends to zero. The last point implies that as the model tends to the bifurcation point, or closer to the onset of oscillations, the range of possible spike delays for the same range of variable ϵ s gets larger.

The theta-neuron is a one-dimensional model, which makes it easy to compute explicitly its phase-response curve (PRC). The infinitesimal PRC is the adjoint of solution and is given by:

$$PRC(t) = 1 - \cos\left(\frac{2\pi t}{T}\right) \quad (19)$$

where T is the period of the oscillation and t ranges from 0 (time of spike 0) to T (time of spike 1). In terms of phase ranging from $-\pi$ to π :

$$PRC(\theta) = 1 + \cos \theta \quad (20)$$

Note that this is exactly the term that pre-multiplies the inputs to the theta-neuron. The PRC of the theta-neuron is positive, which is indicative of SNIC. Interestingly, for the adaptive theta-neuron, when the adaptation threshold is low and the strength is sufficiently high, the PRC can have a significant negative region, implying type II excitability. In fact, in this case, one can find a subcritical

Theta Neuron Model, Fig. 4 PRC theta-neuron. *Left panel:* infinitesimal PRC (iPRC) for the basic theta-neuron computed using the adjoint method. Note that it is positive and symmetric. *Right panel:* iPRC for the theta-neuron

with $I-M$ -like adaptation of sufficient strength. Note that the negative region in the iPRC (delay of spike) and a strong skew to the *right*. Both iPRCs we computed for the same firing frequency

Andronov-Hopf bifurcation leading to the onset of oscillations. So, the theta-neuron with adaptation unites both the type I (SNIC) excitability and type II excitability. For the adapting theta-neuron one cannot really compute the PRC explicitly, but it is easily determined numerically, either through direct simulations or using XPPAUT (Fig. 4).

Who Has Used the Theta-Neuron (Some Examples)

The first use of the model was by Ermentrout and Kopell (1986) to explore the mathematics of parabolic bursting. Subsequently, the theta-neuron was used not only for neural oscillators but also, as a general, for hyper-reduced models of neuronal spike generation. Ermentrout (1996) looked at the theta-neuron as a canonical model for type I excitability and derived the infinitesimal PRC: this has important implications for synaptic mechanisms of synchronization as the strictly positive PRC of the theta-neuron implies inhibition to be synchronizing and excitation leading to non-synchronous states. Gutkin and Ermentrout (1998) used the theta-neuron to show how the type I spike-generating dynamics can lead to highly variable spike timing. They wrote down the stochastic theta-neuron and looked at the

spiking responses to noisy current injections in the excitable regime and as the model is driven past the bifurcation to the oscillatory regime. They found spike times to be highly variable in the excitable regime; the key here was the sensitivity of spike delays to the peri-stimulus noise amplitude. In fact they showed that the variability of the spike times can be much higher than predicted by the linear integrate-and-fire neurons, and high CVs do not require detailed balance of inputs. Lindner et al. (2003) took a closer look at the stochastic derivation and made appropriate corrections for the strong noise case (see above Eqs. 12 and 13). In this case there is an additional noise-induced drift term, implying that noise itself can push the model past the bifurcation into the oscillatory regime and regularize the spike times. Gutkin et al. (2005) used the adaptive theta-neuron to fit experimentally determined PRCs from cortical pyramidal neurons, to explore how the PRC depends on the mean firing rate as well as the strength of the adaptive currents. Stiefel et al. (2009) showed that the adaptive theta-neuron can account for the effects of cholinergic modulation on spike-generating dynamics in cortical neurons.

The theta-neuron has also been used to study the properties of coupled networks. The advantage of this model is that at the spike, it has continuous dynamics (as opposed to the integrate-

and-fire family of models where there is a jump at the spike), making more amenable to analysis. Gutkin et al. (2001) used small circuits of synaptically coupled theta-neurons to understand how the relative timing of the spikes and recurrent excitatory synapses influences the stability of sustained neural activity (correlate of working memory maintenance). Notably they showed that synchrony is not compatible with sustained activity and later that correlated noise can quench sustained activity (Gutkin et al. 2008a, b). Borgers and Kopell (2003) used networks of theta-neurons to study synchronization properties of neuronal oscillators in the gamma band. They developed a “river” technique to analyze how inhibitory synaptic pulses in networks of interneurons and pyramidal neurons might synchronize and create the PING gamma oscillations. Subsequently they used networks of theta-neurons to show how gamma oscillations can lead to competition between incoming stimuli (Borgers et al. 2008; Borgers and Kopell 2008) and gamma synchrony under heterogeneity and noise (Borgers and Kopell 2005). Osan and Ermentrout considered a one-dimensional network of theta-neurons and analyzed how traveling waves can form (Osan et al. 2002). More recently Monteforte and Wolf (2010) studied chaos in networks of sparsely connected theta-neurons in the balanced state, showing that chaos is present in purely inhibitory network and becomes more intense with excitatory neurons added.

do Norte, Natal, RN, Brazil

Synonyms

Amplitude-amplitude coupling; n:m phase-locking; Phase-amplitude coupling; Phase-frequency coupling; Phase-phase coupling

Definition

Brain oscillations of different frequencies can coexist and influence each other. A cross-frequency interaction occurs when a feature from one oscillation (i.e., instantaneous amplitude, phase, or frequency) depends on a feature from another oscillation at a distinct frequency. These phenomena have been collectively called cross-frequency coupling (CFC). There are multiple types of CFC, such as phase-amplitude coupling, amplitude-amplitude coupling, and n:m phase-locking. Several metrics have been devised to quantify CFC.

Detailed Description

The study of the electrical activity produced by the brain dates back to Richard Caton in 1875, who employed a galvanometer to record from the cortex of rabbits (Geddes 1987). Neuronal spikes and extracellular field potentials have been since recorded from several brain regions of different species, and spectral analyses have shown that they are often rhythmical. Scientists usually classify brain oscillations according to their frequency, waveform shape, local of origin, and associated behavior. Among them, the hippocampal formation of rats and mice produces a prominent rhythm in the 4–12 Hz range when animals explore their surroundings or during REM sleep, the so-called theta oscillations (Buzsáki 2002). In addition, faster oscillations appear associated with theta waves, such as gamma rhythms (30–100 Hz) and high-frequency oscillations (HFOs; 120–160 Hz) (Scheffer-Teixeira and Tort 2017). A new field of higher-level analysis emerged with the discovery that oscillations of distinct frequencies might not only coexist but also interact with each other (Canolty and Knight 2010; Hyafil et al. 2015). Oscillatory interaction can occur through any of the main features of a rhythm: amplitude, phase, or frequency (Fig. 1). These phenomena are collectively known as cross-frequency coupling (CFC). To date, the most studied CFC types are phase-amplitude coupling, amplitude-amplitude coupling, and n:m phase-locking, while other CFC types remain to be further explored (Hyafil et al. 2015).

Measures of synchronization between brain waves were first motivated by the study of coupled oscillators (Ermentrout and Kopell 1991; Tass et al. 1998; Strogatz 2000; Rosenblum et al. 2001). However, despite local regularities and short-term predictability, neural oscillations do not behave as stationary sinusoids and are not easily described by a set of equations. Rather, local field potentials (LFPs) are subject to several sources of variability, most unknown or uncontrolled, and exhibit noisy states and chaotic components. While not formally demonstrated, the coupling between brain signals is believed to

Theta-Gamma Cross-Frequency Analyses (Hippocampus), Fig. 1 (continued)

fall into the category of “weakly coupled oscillators” (Hoppensteadt and Izhikevich 1998). Several approaches were proposed to infer the existence and quantify the degree of coupling based on a general statistical sense: two oscillations are assumed to be coupled if knowledge of the state of one oscillation predicts the state of another oscillation. Notice that this statistical definition ignores the underlying mechanisms. In particular, it does not inform about directionality and causality, that is, whether an oscillation modulates, is modulated, or both, whether coupling is externally or internally driven, direct or indirect.

The following sections summarize common CFC metrics. For simplicity, we often refer to theta and gamma as canonical examples of slow and fast oscillations of interest, but the metrics are general enough to be applied to any cross-frequency pair.

Filtering and Feature Extraction

Phase, frequency and amplitude can be extracted from brain signals (LFP, EEG, MEG) using standard signal processing techniques. The first step is to filter the raw data into the desired frequency range, which can be achieved by many different types of filters. Of note, to detect phase-amplitude coupling, the bandwidth of the filtered fast oscillation component (i.e., gamma) must include its peak frequency (f_γ) and the side-band frequencies at $f_\gamma \pm f_\theta$, where f_θ is the frequency of the slow oscillation (i.e., theta) (Berman et al. 2012; Aru et al. 2015).

After filtering, the phase and amplitude time series can be obtained from its analytic representation, defined as $Z(t) = X(t) + iH(X(t))$, where the real part, $X(t)$, is the filtered signal and the imaginary part, $H(X(t))$, its Hilbert transform, which is a version of $X(t)$ shifted by -90° . The instantaneous amplitude at each time t is defined as

the absolute value of $Z(t)$, given by $|Z(t)| = \sqrt{X(t)^2 + H(X(t))^2}$, while the instantaneous phase at time t is defined as $\varphi(t) = \tan^{-1}(H(X(t))/X(t))$. Notice that $Z(t)$ can be expressed in polar form as $Z(t) = |Z(t)|e^{i\varphi(t)}$. Alternatively, the amplitude and phase time series can be obtained as the absolute value and angle of a complex wavelet transform (with the due caution of the filtered bandwidth). The instantaneous phase can also be estimated by linear interpolation: peaks and valleys of the filtered signal are first identified and set to predefined phases (e.g., 0° for peak and 180° for valley). Subsequently, the samples between each peak-to-valley and valley-to-peak interval are attributed to linearly spaced phase values (Belluscio et al. 2012).

Finally, the instantaneous frequency is estimated from the first derivative of the unwrapped phase time series: $f(t) = \frac{1}{2\pi} \frac{d\varphi(t)}{dt}$.

CFC Metrics

Several of the metrics below assume that the signal has already been band-pass filtered into the theta and gamma ranges of interest and the relevant features extracted (i.e., phase and amplitude time series). Ideally, the frequency boundaries of the band-pass filter should be selected based on visual inspection of the power spectrum, so as to encompass the power “bumps” at the corresponding frequencies. However, while theta is usually associated with a discernable power peak, the frequency boundaries of gamma activity are often difficult to determine due to the much lower signal-to-noise ratio, especially for the faster gamma subbands. In these cases, the choice of the filtered band may be based on the inspection of comodulation maps (see below) or on previous studies.

and amplitude series extracted using the Hilbert transform. The instantaneous frequency time series is derived from the phase time series. (b) Each subpanel depicts one possible CFC type by means of simulated data

Theta-Gamma Cross-Frequency Analyses (Hippocampus), Fig. 2 (continued)

Phase-Amplitude Coupling (PAC)

PAC has been identified in different types of brain signals and received much attention in recent literature. We summarize some of the PAC metrics in this section (Fig. 2), but we note that the list is nonexhaustive and novel metrics are continuously being devised.

Measures Based on the Maximal and Minimal Values of the Amplitude Distribution

Several PAC metrics require first computing the mean gamma amplitude as a function of the phase of the theta cycle. This is obtained by partitioning theta phases into nonoverlapping bins and calculating the average gamma amplitude (A_j) associated with each phase bin j . Phase bins are usually 10° to 30° wide.

A straightforward metric for PAC strength is obtained by taking the ratio between the maximum (A_{max}) and minimum (A_{min}) average gamma amplitude within the theta cycle (Lakatos et al. 2005):

$$PAC_{strength} = \frac{A_{max}}{A_{min}}$$

Notice that this ratio is not bounded. Other variants include ratios that vary between 0 and 1, such as:

$$PAC_{strength} = \frac{A_{max} - A_{min}}{A_{max}}$$

and

$$PAC_{strength} = \frac{A_{max} - A_{min}}{A_{max} + A_{min}}$$

Modulation Index (MI)

Tort et al. (2008) defined the PAC MI as an adaptation of a phase synchrony metric based on information theory introduced by Tass et al. (1998). The MI first requires normalizing the average

amplitude per phase bin (A_j) to generate a discrete probability-like distribution (P):

$$p_j = \frac{A_j}{\sum_{j=1}^{N_b} A_j}$$

whose Shannon's entropy ($H(P)$) is:

$$H(P) = - \sum_{j=1}^{N_b} p_j \log(p_j)$$

where j indexes the phase bins and N_b is the total number of bins. The PAC MI is obtained as an "inverted" normalization of $H(P)$:

$$PAC_{strength} = MI = \frac{H_{max} - H(P)}{H_{max}}$$

where $H_{max} = H(U) = \log(N_b)$ is the maximum possible entropy, achieved for a uniform distribution $U(p_j = 1/N_b \text{ for all } j)$. Thus, $MI = 0$ when the phase-amplitude distribution is uniform, and $MI = 1$ in the (hypothetical) case in which gamma only appears in one phase bin of theta ($p_k = 1$ for a single bin k , and $p_j = 0$ for all $j \neq k$).

The MI is related to the Kullback-Leibler divergence (D_{KL}) by the equation $D_{KL}(P, U) = \log(N_b) - H(P)$. In other words, the MI can be viewed as the normalized Kullback-Leibler divergence between the uniform distribution and the observed phase-amplitude distribution:

$$MI = \frac{D_{KL}(P, U)}{H_{max}}$$

In practical terms, a Dirac-like distribution is improbable for real LFP signals and the MI values are skewed towards zero. In LFP recordings, significant theta-gamma MI values usually lie between 10^{-3} and 10^{-2} ; values around 10^{-4} are considered weak and may be borderline for statistical significance, especially for short epochs. The

theta phase modulates gamma amplitude. The phase of the gamma amplitude time series is extracted after demeaning. (b) Panels depict different measures for PAC (see text)

MI can also be computed using the distribution of gamma bursts, that is, the counts of events per theta phase where gamma amplitude is higher than a threshold.

Mean Vector Length (MVL)

Canolty et al. (2006) introduced a PAC metric based on the complex time series $A_\gamma(t)e^{i\varphi_\theta(t)}$, where $A_\gamma(t)$ is the instantaneous gamma amplitude at time t and $\varphi_\theta(t)$ the instantaneous theta phase. The existence of PAC can be visually inferred by plotting these vectors in the complex plane: if theta and gamma are phase-amplitude coupled, the higher gamma amplitude in a subset of theta phases leads to an asymmetric distribution of vector lengths (amplitude values) around the origin. PAC strength can be estimated by measuring this asymmetry by means of the length of the mean vector:

$$PAC_{strength} = \left\| \frac{1}{N} \sum_{j=1}^N A_\gamma(t_j) e^{i\varphi_\theta(t_j)} \right\|$$

where N is the number of time points. The absence of PAC is characterized by a roughly uniform circular distribution of individual vectors, which will cancel each other out and lead to a low MVL. On the other hand, an asymmetry (polarization) in the complex plane leads to a resultant mean vector of larger length. The larger the polarization, the larger the MVL.

In the original formulation, the MVL was normalized and expressed as z-score in relation to a surrogate distribution of 200 MVL values (obtained from $A_\gamma(t)$ and $\varphi_\theta(t)$ not matched in time) (Canolty et al. 2006). Thus, the normalized metric reflected the statistical significance of PAC more than its strength.

Phase-locking Value (PLV)

In addition to being used to assess phase synchrony (Lachaux et al. 1999), the PLV can be readily adapted to measure PAC strength (Vanhatalo et al. 2004; Cohen 2008; Penny et al. 2008). As the MVL, the PLV also relies on computing the length of a mean vector, but in this case the time series is composed of unitary vectors. To

compute the PLV, the instantaneous gamma amplitude must be first demeaned (or detrended), so that it assumes positive and negative values. For the case of a theta-modulated gamma, the demeaned amplitude time-series oscillates around zero at theta frequency. The PLV is the length of the mean over unit vectors whose angle is the difference between the phase of theta (φ_θ) and the phase of gamma amplitude (φ_{A_γ}):

$$PAC_{strength} = \left\| \frac{1}{N} \sum_{j=1}^N e^{i\Delta\varphi(t_j)} \right\|$$

where $\Delta\varphi(t_j) = \varphi_{A_\gamma}(t_j) - \varphi_\theta(t_j)$. The more the gamma amplitude is phase-locked to theta, the more constant their phase difference is. The PLV is 1 if $\Delta\varphi(t_j)$ is exactly constant for all t , and 0 if the circular distribution of phase differences is uniform.

Envelope-Signal Correlation (ESC)

The ESC metric is the correlation between the theta-filtered signal (x_θ) and the amplitude envelope of gamma (A_γ) (Bruns and Eckhorn 2004):

$$\begin{aligned} PAC_{strength} &= \text{corr}(x_\theta, A_\gamma) \\ &= \frac{1}{N} \sum_{j=1}^N \frac{(x_\theta(t_j) - \bar{x}_\theta)(A_\gamma(t_j) - \bar{A}_\gamma)}{\sigma_{x_\theta} \sigma_{A_\gamma}} \end{aligned}$$

Penny et al. (2008) introduced a variation that normalizes for the amplitude of theta, which is achieved by correlating gamma amplitude with the cosine of the instantaneous theta phase ($\cos(\varphi_\theta)$):

$$PAC_{strength} = \text{corr}(\cos(\varphi_\theta), A_\gamma)$$

The correlation metrics vary between -1 and 1 ; when gamma amplitude is maximal near the trough of theta, the correlation is negative, while positive correlations occur when gamma amplitude is maximal near the theta peak. The correlation may be zero even in the presence of phase-amplitude coupling if gamma has maximal amplitude when theta crosses zero (i.e., at 90° from the cycle peak or

trough), the so-called “null phases” (Cohen 2008; Penny et al. 2008; Tort et al. 2010).

General Linear Model (GLM)

To circumvent the fact that the correlation metrics are not well suited to detect coupling if gamma is maximal at the null phases (i.e., zero crossings at $\cos(\pi/2)$ and $\cos(3\pi/2)$), Penny et al. (2008) proposed a generalization using GLM. In this framework, gamma amplitude is modeled as:

$$A_\gamma = \beta_0 + \beta_1 \cos(\varphi_\theta) + \beta_2 \sin(\varphi_\theta) + \varepsilon$$

where β_j ($j = 0, 1, 2$) are the regression coefficients and ε is the error (noise) term. Since the sine and cosine of the same phase is never simultaneously zero, the GLM metric has no “null phases.” Finding the regression coefficients can be achieved by standard linear regression techniques. The GLM-based PAC metric is then defined as:

$$PAC_{strength} = \frac{SS(A_\gamma) + SS(\varepsilon)}{SS(A_\gamma)}$$

where $SS(A_\gamma)$ is the explained sum of squares of the model and $SS(\varepsilon)$ the sum of squared errors (residuals).

Envelope-Signal Coherence

PAC can also be estimated from the coherence spectra between the instantaneous gamma amplitude time series and the unfiltered LFP signal (Colgin et al. 2009). The standard (i.e., Fourier-based) phase coherence between two signals X and Y is defined as:

$$C_{XY}(f) = \frac{\left\| \langle F_X(f) \cdot \overline{F_Y(f)} \rangle \right\|}{\left\| \langle F_X(f) \rangle \right\| \left\| \langle F_Y(f) \rangle \right\|}$$

where $F_X(f)$ and $F_Y(f)$ are the Fourier transforms at frequency f of X and Y, respectively. Oftentimes the “magnitude-squared” coherence (C_{XY}^2) is used. Both C_{XY} and C_{XY}^2 vary between 0 and 1. A theta-gamma coupling metric can then be obtained as the average coherence in the theta frequency range.

Power Spectral Density (PSD) of the Amplitude Envelope

If phase-modulated by theta, gamma amplitude tends to oscillate at theta frequency. Therefore, decomposing A_γ into its frequency components by means of Fourier spectral analysis may be used to infer PAC (Cohen 2008; Tort et al. 2010). Similarly to the coherence metric above, in this framework PAC is estimated by integrating (or averaging) the PSD of A_γ over the theta range. Such a method may provide meaningless estimates if the A_γ PSD has no peak at theta frequency.

Mutual Information

Theta-gamma PAC can be assessed using Shannon’s mutual information, which computes how much the joint probability of phase and amplitude values deviates from the product of their marginal distributions. By definition, mutual information is zero for independent variables (joint probability equal to the product of the marginal probabilities). To estimate the joint and marginal probability distributions, the range of phase (i.e., 0 to 2π) and amplitude values must be first binned; each bin count is subsequently normalized by the total counts ($N_{\text{total}} = \text{sampling rate} \times \text{epoch length}$), yielding:

$$p(\varphi_i) = \frac{N_{\varphi_i}}{N_{\text{total}}}, \quad p(a_j) = \frac{N_{a_j}}{N_{\text{total}}}, \quad \text{and}$$

$$p(\varphi_i, a_j) = \frac{N_{\varphi_i \cap a_j}}{N_{\text{total}}},$$

where N_{φ_i} is the number of counts in phase bin i , N_{a_j} the number of counts in amplitude bin j , and $N_{\varphi_i \cap a_j}$ the number of joint counts. Mutual information is then estimated as:

$$PAC_{strength} = I(\Phi; A) = \sum_{i=1}^{M_b} \sum_{j=1}^{N_b} p(\varphi_i, a_j) \log \left(\frac{p(\varphi_i, a_j)}{p(\varphi_i)p(a_j)} \right)$$

where M_b and N_b are the number of phase and amplitude bins, respectively. This estimator is

considered naïve since it does not correct for the positive bias associated with the use of finite samples to estimate the probability distributions; more sophisticated estimators that correct for such bias can be used (Panzeri et al. 2007).

Comodulation Maps

Comodulation maps, or “comodulograms,” are 2D heatmaps that simultaneously express PAC strength values for multiple frequency pairs, and can be constructed for any of the metrics above (Fig. 3). Usually, the x-axis represents the phase-providing frequency and the y-axis the amplitude-modulated frequency, while the color represents PAC strength. In some cases, the color represents the statistical significance of PAC.

Phase-Phase Coupling (PPC)

Cross-frequency PPC is defined as a consistent phase relation between multiple gamma cycles within theta cycles. This type of CFC is also called $n:m$ phase-locking. For example, 1:5 phase-locking is characterized by five gamma cycles consistently nested within theta cycles, in which each gamma cycle (i.e., the first, the second, etc.) starts/finishes at a similar theta phase across cycles. In PPC, theta and gamma would adjust their instantaneous frequencies in order to keep the same ratio of cycles; therefore, PPC can also be considered as frequency locking.

Mean Radial Distance ($R_{n:m}$)

The mean radial distance ($R_{n:m}$) – also called mean resultant length – is a common metric of

Theta-Gamma Cross-Frequency Analyses (Hippocampus), Fig. 3 Comodulation maps. PAC strength for several pairs of phase- and amplitude-providing frequency ranges can be simultaneously depicted by means of a bidimensional pseudocolor map, in which the color scale

denotes the value of the PAC metric (in this example, the MI). The coordinates usually represent the center frequency of the filtered signals. Comodulation maps can also be constructed for other CFC types

PPC strength. This metric is similar to the PLV, but with phasors defined as unitary vectors whose angle is the phase difference between accelerated theta and gamma phases (Tass et al. 1998):

$$PPC_{strength} = R_{n:m} = \left\| \frac{1}{N} \sum_{j=1}^N e^{i\Delta\varphi_{nm}(t_j)} \right\|$$

where $\Delta\varphi_{nm}(t_j) = n\varphi_\gamma(t_j) - m\varphi_\theta(t_j)$, and $n\varphi_\gamma$ ($m\varphi_\theta$) represents the phase of gamma (theta) accelerated n (m) times. In the case of theta-gamma PPC, $R_{n:m}$ “curves” are usually obtained by varying m with $n = 1$ (Belluscio et al. 2012; Scheffer-Teixeira and Tort 2016). PPC strength can also be expressed for multiple n and m values by means of 2D heatmaps (Palva et al. 2005).

Shannon Entropy-Based Index

Tass et al. (1998) proposed two metrics of $n:m$ phase-locking. One of the metrics is defined as an inverted normalization of the Shannon entropy of the probability distribution of $\Delta\varphi_{nm}$ (Ψ_{nm}):

$$PPC_{strength} = \frac{H_{max} - H(\Psi_{nm})}{H_{max}}$$

where H_{max} is the entropy of the circular uniform distribution. The probability distribution Ψ_{nm} is estimated by binning the circle into non-overlapping phase bins, counting the number of $\Delta\varphi_{nm}$ values within each bin, and normalizing the bin counts by the total counts. Notice that this metric is essentially the same as the PAC MI (actually, the latter was adapted from the former), but applied to the circular distribution of phase difference values instead of amplitude values.

Conditional Probability-Based Index

The second measure introduced by Tass et al. (1998) relies on assessing instantaneous gamma phases conditioned to fixed theta phase bins. In this framework, the theta phases are first binned into N_θ nonoverlapping bins; then, the following vector is computed for each phase bin θ_l :

$$R_{\theta_l} = \frac{\sum_{j=1}^{N_l} e^{i\varphi_\gamma(t_j)}}{N_l}$$

where $\varphi_\gamma(t_j)$ is the instantaneous gamma phase at t_j , and N_l is the total number of timestamps t_j belonging to θ_l (i.e., t_j is such that $\varphi_\theta(t_j) \in \theta_l$). Therefore, each theta phase bin is associated with a mean vector over phasors whose angles are the instantaneous gamma phases falling in it. If gamma has the exact same phase within a fixed theta phase bin, the magnitude of R_{θ_l} is 1. On the other hand, if $\varphi_\gamma(t_j)$ values are random (i.e., gamma is not phase-locked), the unit vectors will cancel each other out, and $|R_{\theta_l}|$ will be small. The PPC metric is defined as the average vector length over all theta phase bins:

$$PPC_{strength} = \frac{\sum_{l=1}^{N_\theta} |R_{\theta_l}|}{N_\theta}$$

Pairwise Phase-Consistency

Phase-locking metrics based on the addition of phase difference vectors are positively biased for small samples. To circumvent this issue, Vinck et al. (2010) proposed the pairwise phase consistency, which is defined as the average dot product over all vector pairs, or, equivalently, the average cosine between all vector pairs. Scheffer-Teixeira and Tort (2016) recently used Vinck’s metric to measure $n:m$ phase-locking by applying it to the difference between accelerated gamma and theta phases ($\Delta\varphi_{nm}$):

$$PPC_{strength} = \frac{2}{N(N-1)} \sum_{j=1}^{N-1} \sum_{k=(j+1)}^N \cos(\Delta\varphi_{nm}(t_j) - \Delta\varphi_{nm}(t_k))$$

where N is the total number of time samples. If the accelerated phase differences $\Delta\varphi_{nm}$ are constant, meaning perfect $n:m$ phase-locking, $\cos(\Delta\varphi_{nm}(t_j) - \Delta\varphi_{nm}(t_k)) = \cos(0) = 1$ and consequently $PPC = 1$. If $\Delta\varphi_{nm}$ values are random and uniformly distributed over the circle, the expected value of PPC is 0.

Mutual Information

Theta-gamma PPC can also be measured using Shannon's mutual information in a similar way as described above for PAC assessment. Namely, the joint and marginal probability distributions are first estimated from phase bin counts ($N_{\text{total}} = \text{sampling rate} \times \text{epoch length}$):

$$p(\varphi_{\theta_i}) = \frac{N_{\theta_i}}{N_{\text{total}}}, \quad p(\varphi_{\gamma_j}) = \frac{N_{\gamma_j}}{N_{\text{total}}}, \quad \text{and} \\ p(\varphi_{\theta_i}, \varphi_{\gamma_j}) = \frac{N_{\varphi_{\theta_i} \cap \varphi_{\gamma_j}}}{N_{\text{total}}},$$

and mutual information is subsequently calculated as:

$$PPC_{\text{strength}} = I(\Phi_{\theta}; \Phi_{\gamma})$$

$$= \sum_{i=1}^M \sum_{j=1}^N p(\varphi_{\theta_i}, \varphi_{\gamma_j}) \log \left(\frac{p(\varphi_{\theta_i}, \varphi_{\gamma_j})}{p(\varphi_{\theta_i})p(\varphi_{\gamma_j})} \right)$$

Amplitude–Amplitude Coupling (AAC)

Correlation Between Amplitude or Power Values

Theta-gamma AAC can be estimated as the correlation between the amplitude envelopes of theta (A_{θ}) and gamma (A_{γ}) (Bruns et al. 2000; Bruns and Eckhorn 2004):

$$AAC_{\text{strength}} = \text{corr}(A_{\theta}, A_{\gamma}) \\ = \frac{1}{N} \sum_{j=1}^N \frac{(A_{\theta}(t_j) - \overline{A_{\theta}})(A_{\gamma}(t_j) - \overline{A_{\gamma}})}{\sigma_{A_{\theta}} \sigma_{A_{\gamma}}}$$

Alternatively, the correlation can be performed using integrated power over the desired frequency ranges. To that end, the analyzed epoch must be first partitioned into contiguous, nonoverlapping windows and Fourier-transformed within windows to compute the power spectra (Masimore et al. 2004). With either framework, an amplitude–amplitude comodulogram can be plotted by representing the correlation coefficients of multiple frequency pairs by means of a 2D heatmap (Masimore et al. 2004).

Phase-Locking of Amplitude Envelopes

The phase-locking value (PLV) can also be adapted to measure AAC (Jirsa and Müller 2013). Instead of using the filtered signal, the phase time series are extracted from the detrended amplitude envelopes of theta (A_{θ}) and gamma (A_{γ}). AAC is then estimated as:

$$AAC_{\text{strength}} = \left\| \frac{1}{N} \sum_{j=1}^N e^{i(\varphi_{A_{\theta}}(t_j) - \varphi_{A_{\gamma}}(t_j))} \right\|$$

Mutual Information

As all CFC types, theta-gamma AAC can also be assessed by mutual information. To that end, the range of amplitude values of each oscillation must be binned into nonoverlapping bins. Estimations of the joint and marginal probability of amplitude values are then obtained by normalizing bin counts and used to compute the mutual information.

Phase–Frequency Coupling (PFC), Amplitude–Frequency Coupling (AFC), and Frequency–Frequency Coupling (FFC)

PFC, AFC, and FFC have been considerably less explored than the other CFC types (Hyafil et al. 2015). Nevertheless, several of the metrics described above can be adapted to measure these interactions. For instance, Hyafil (2015) proposed that standard PAC measures could assess PFC by using the instantaneous frequency time series instead of the amplitude envelope. More generally, the values achieved by each oscillatory feature (e.g., amplitude or frequency) can always be binned and transformed into probability distributions to allow for computing the mutual information.

Sources of Biases and Spurious Coupling

There are several possible sources of bias and spurious results in CFC research (Kramer et al. 2008; Aru et al. 2015; Hyafil 2015; Scheffer-Teixeira and Tort 2016); among them:

1. *Asymmetric waveform*: recent studies have explored the influence of waveform shape on CFC measures (Gerber et al. 2016; Lozano-

- Soldevilla et al. 2016; Scheffer-Teixeira and Tort 2016; Cole et al. 2017). For instance, hippocampal theta oscillations are asymmetric, in that the rising phase is faster than the falling one, and such asymmetry increases with locomotion speed (Belluscio et al. 2012). Waveform asymmetry may induce spurious PAC and PPC, since the filtered signals will reflect a set of harmonic waves that naturally couple to the fundamental oscillation and to each other (Aru et al. 2015; Scheffer-Teixeira and Tort 2016). Another side-effect of asymmetric waveforms is nonuniform phase distributions, which may produce biased CFC estimates (van Driel et al. 2015).
2. *Sharp edges*: Kramer et al. (2008) recognized that sharp signal deflections are a potential confound factor in CFC analyses. The sharp edges in EEG and LFP signals may have either biological origin (e.g., event-related potentials or spike-and-wave mu rhythms) or be due to stimulation artifacts. At any event, the abrupt deflections give rise to spurious fast oscillatory activity in filtered signals, which in turn may mislead CFC estimates.
 3. *Nonmeaningful features and filtering-induced sinusoidality*: standard filtering methods tend to produce sinusoid-like signals even in the absence of genuine brain oscillations in the filtered frequency range. As a consequence of the sinusoidality imposed by the filter, the phase and frequency time series may temporally appear as coupled and lead to PPC overestimation, especially in short time epochs (Scheffer-Teixeira and Tort 2016; Hyafil 2017).
 4. *Wrong bandwidth choice*: In PAC analysis, the filtered bandwidth should contain both the amplitude-modulated frequency and the side bands (modulated frequency $\pm$ modulating frequency). Therefore, narrowly filtered frequency bands may not detect genuine PAC (Berman et al. 2012; Aru et al. 2015). Curiously, however, Hyafil (2015) pointed out that PFC can be mistaken as PAC in narrowly filtered signals, since cyclic variations of the instantaneous gamma frequency outside the filtered range will be associated with cyclic amplitude variations. For a similar reason, Hyafil (2015) further pointed out that variations in instantaneous frequency may be mistaken as AAC.
 5. *Phase slips and frequency spikes*: Instantaneous frequency is estimated as the first derivative of the phase time series. Fast signal perturbations may cause “jumps” in the phase time series, the so-called “phase slips” (Hurtado et al. 2004). Such events produce large deviations of the instantaneous frequency (“frequency spikes”), much above or below the filtered frequency range (it may even assume negative values), even though the frequency of the rhythm may not change on a larger time-scale (see Fig. 1A for an actual example). Of note, phase slips and frequency spikes are also common in aperiodic or noisy signals. Abundant phase slips may thus bias the assessment of frequency coupling. One method to overcome this issue is to detect the associated frequency spikes and smooth them out (Hurtado et al. 2004).
- Ideally, the investigated oscillations (i.e., theta and gamma) should exist in the analyzed signal, as inferred by peaks in the power frequency spectrum. As a rule of thumb, CFC estimates are most “trustable” when one can observe such interaction by visual inspection of raw (unfiltered) signals. Theta- and gamma-filtered signals can be plotted along with the unfiltered signal to facilitate such inspection.
- Statistical Assessment**
- Statistical analyses may be used to infer if CFC exists (i.e., beyond chance levels) or to compare CFC strength among different groups (e.g., different manipulations, cognitive states, frequency pairs, or brain regions). While the latter can be performed with standard statistical tests, the former usually requires the construction of surrogate distributions of coupling strength. As a general rule, a good surrogate method should preserve data continuity and spectral properties, as well as it should use the same epoch length as the original data (Scheffer-Teixeira and Tort 2016). A typical surrogate procedure is to analyze theta and

gamma time series not matched in time. The existence of theta-gamma coupling is then assessed by comparing the actual CFC metric with the chance distribution of surrogate values.

On the Choice of the CFC Metric

As summarized above, several CFC metrics were proposed to quantify the presence or absence of interacting brain oscillations. However, the repertoire of metrics may lead to confusion when choosing one of them, which motivated some comparative studies (e.g., Penny et al. 2008; Tort et al. 2010; Onslow et al. 2011). As a starting point, one can assume that a good metric should present (1) unbiased estimators, (2) tolerance to noise, and (3) strength representation (i.e., different coupling levels are separately represented by the metric). Regarding these characteristics, we make the following observations:

(1) Vinck et al. (2010) showed that the metrics based on vector addition, such as MVL, PLV, and coherence, are positively biased for shorter epochs. (Although Vinck et al. have originally referred to phase synchrony metrics devised for oscillations of the same frequency, these metrics were eventually adapted to measure PAC and inherited the same caveats.) This is because – in the absence of coupling – a large enough number of vectors should be sampled to produce a null resultant vector. But we note that the positive bias for short epochs is not unique to these metrics. In general, to confidently assess PAC, one needs to analyze enough cycles to infer whether consistent variations of the gamma amplitude exist within theta cycles. In practice, the instantaneous gamma amplitude is never constant within the time window of a theta cycle (~125 ms), and hence, a phase-amplitude distribution computed using a single theta cycle will never be uniform. Therefore, the presence of nonuniform phase-amplitude distributions should be interpreted with caution for short time epochs and, most importantly, must be compared with chance distributions (c.f., last section above). While we cannot advocate a minimal epoch length for CFC analysis due to

the great variability of brain signals, metrics, and research settings, we recommend always to perform internal checks using real and simulated data, such as to assess metric convergence as a function of the analyzed epoch length and chance distributions (Tort et al. 2010; Scheffer-Teixeira and Tort 2016).

(2) The addition of noise to phase-amplitude coupled signals may differentially affect some PAC metrics. Tort et al. (2010) found that PLV, ESC, GLM, and coherence are negatively affected by noise, which leads them to underestimate PAC strength. On the other hand, the ratio-based metrics, MI and MVL, are more tolerant to noise, while the amplitude PSD overestimates PAC strength with higher noise levels. This occurs because the added noise increases power in all frequency bands.

(3) Some measures may better track “coupling consistency” across cycles, defined as the proportion of theta cycles in which gamma appears modulated by theta, but are less sensitive to “coupling strength,” defined as the magnitude of the amplitude modulation within theta cycles (Tort et al. 2010). For instance, PLV and coherence both are based on the phase transformation of the gamma amplitude. Because of that, the amplitude modulations will be treated as cycles with phases varying from 0° to 360°, irrespective of the magnitude (e.g., an amplitude variation of $\pm 10\%$ or $\pm 50\%$ from the mean may lead to similar phase time series). Correlation-based indexes, such as GLM and ESC, also do not represent the coupling strength well, but for a different reason: the presence of higher modulations shifts the regression slope or the Y-intercept, but does not necessarily change the correlation/regression coefficient (Tort et al. 2010). Finally, by design, some PAC metrics such as the MVL and the amplitude PSD take into account the absolute amplitude of gamma and will thus also depend on gamma power irrespective of the “relative” coupling strength, as defined by the percentage of change from the mean amplitude (Tort et al. 2010).

Of note, some may also be interested that the metric is capable of detecting multimodal coupling (e.g., when gamma amplitude has two maxima within a theta cycle). By their definitions, the MI and the mutual information would be better suited in these cases (Tort et al. 2010).

Despite these particularities, it should be noted that hippocampal theta-gamma PAC is usually a phenomenon robust enough to be detected by any of the metrics. Ultimately, one should choose a metric whose advantages and limitations are well understood, and also bear in mind that the very definition of CFC will depend on this choice. In this sense, since it is presently unclear whether the assessment of “coupling consistency” or “coupling strength” (c.f. definitions above) would be cognitively more relevant, we cannot point to a single PAC metric as the best one.

Lastly, we note that PPC has received less attention regarding comparative studies among metrics. Shannon entropy, conditional probability, and mutual information-based indexes are not as widely used as the mean radial distance. The mean radial distance, however, is based on vector addition and is thus a positively biased estimator (small epochs result in higher values). Recently, Scheffer-Teixeira and Tort (2016) showed computationally that Vinck’s pairwise phase consistency could be adapted and used as an unbiased index for PPC.

Novel CFC Metrics

The study of cross-frequency interactions is an active field of research, which involves scientists working at different levels, brain regions, species, and brain signals (e.g., EEG, ECOG, LFP, MEG). CFC has also been described outside the brain, such as in the gut (Huizinga et al. 2014), and also in non-biological fields such as atmospheric dynamics (Paluš 2014). As an active field, new CFC metrics are continuously being elaborated; there are certainly far more CFC metrics than the ones summarized in this chapter. Important advances include metrics designed to infer coupling directionality (Paluš 2014; Jiang et al. 2015; Li et al. 2016), to improve time-resolution (Voytek et al. 2013; Dvorak and Fenton 2014; Samiee and Baillet 2017), to provide confidence

intervals and higher statistical rigor (Kramer and Eden 2013; van Wijk et al. 2015), to avoid standard filters by using autoregressive models (Tour et al. 2017) or empirical mode decomposition (Pittman-Polletta et al. 2014), and to cope with multiple channel data and spatial filtering (Cohen 2017).

Time Constant, Tau, in Neuronal Signaling

William R. Holmes

Department of Biological Sciences, Ohio University, Athens, OH, USA

Definition

The membrane time constant τ with $\tau = R_m C_m$ is a measure of the rate of voltage decay (or charging) in a cell (Rall 1977). Quantitatively τ is the time it takes for the voltage to decay to 1/e or 37% of its initial value in an isopotential or uniformly polarized cell.

Detailed Description

As given in the definition above, the membrane time constant τ with $\tau = R_m C_m$ is a measure of the rate of voltage decay (or charging) in a cell. Quantitatively τ is the time it takes for the voltage to decay to 1/e or 37% of its initial value in an isopotential or uniformly polarized cell. This can be seen from the solution of the differential equation for a uniformly polarized cell,

$$C_m dV/dt + V/R_m = 0$$

which can be solved as

$$\begin{aligned} V(t) &= V_0 \exp(-t/\tau) \text{ or } V(t) \\ &= V_\infty - (V_\infty - V_0) \exp(-t/\tau) \end{aligned}$$

when initial voltage is V_0 and voltage decays to zero in the first equation or to a resting voltage V_∞ in the latter equation. The latter equation can also be used to describe voltage charging in response to current injection by letting V_0 be the resting potential and V_∞ be the steady-state voltage which is $V_0 + IR_N$ where I is the injected current and R_N is input resistance.

The importance of τ is that it determines how synaptic inputs are integrated in time (temporal summation). If τ is small, individual inputs decay quickly and will not sum, but if τ is large, inputs will decay slowly and are much more likely to sum.

Because $\tau = R_m C_m$, its value will depend on the density of open ion channels in the membrane as well as on membrane capacity. However, τ does not depend on membrane area; it has units of time, typically milliseconds.

Voltage decay depends strictly on τ only for a uniformly polarized cell and becomes more complicated when voltage is not spatially uniform. While voltage falls to 37% of its initial value in time τ in a uniformly polarized cell, voltage falls to 16% of its final value in time τ in an infinite cable; in a finite cable, the decay rate lies in between, although the final decay rate does reflect τ . Interestingly, when voltage is not spatially uniform, the total charge will still decay according to τ .

²Department of Applied Mathematics, University of Waterloo, Waterloo, ON, Canada

³Département de Mathématiques et de Statistique, Université de Montréal, QC, Canada

Definition

A time-delayed neural network is a model for a biological or artificial neural network which is formulated in terms of a delay differential equation, i.e., an equation relating the derivative of the state of the system to the state of the system at some past times. Time delays can have profound effect on the network behavior; in particular, they can induce nonlinear transient or steady-state oscillations.

Detailed Description

Biological Background

In biological neural networks, if the axon is thick and myelinated, then the transportation of signals is fast. However, a considerable portion of the axons (estimated range: 20–40 percent) are very fine myelinated fibers or unmyelinated ones. These axons play quite an important role since they give rise to long delays, up to 100–200 ms (Herz et al. 1989; Miller 1994; Swadlow and Waxman 2012). In addition, there may be (post) synaptic delays, so that long-term potentiation even occurs if the signal from the source neuron has arrived some time before the target neuron becomes active. In general, axonal signal propagation corresponds to discrete time delays, while diffusion processes across the synapses and along the dendrites are modeled by distributed delays. Time delays are also omnipresent in artificial

Time Histogram

► Estimation of Neuronal Firing Rate

neural networks and, in particular, in the electronic hardware implementation, due to the finite propagation velocity of neural signals and due to the finite switching speed of amplifiers (neurons).

Time-delayed network models and prototypes. Consider a network of n neurons modeled by the equations:

$$\begin{aligned}\dot{x}_i(t) &= f_i(x_i(t)) + \sum_{j=1}^n f_{ij}(x_i(t), x_j(t)), i \\ &= 1, \dots, n,\end{aligned}$$

in which x_i represents all the variables describing the physical state of the cell body of the i -th neuron in the network. For example, in the standard Hodgkin-Huxley model, it would represent the membrane voltage and gating variables. The function f_i represents the intrinsic dynamics of the i -th neuron, and the function f_{ij} , often called the coupling function, represents the input to the i th neuron from the j th neuron. Neurons can be connected via chemical synapses or gap junctions, giving rise to different forms of the coupling functions. There are also different ways to incorporate the time delays in a neural network model, to reflect the different sources of delay in the neural system. For example, time delays due to propagation of action potentials can be incorporated into the model by including spatial dependence of the variables or multiple compartments representing different parts of the neuron (Ermentrout and Terman 2010). However, if we are primarily interested in the effect of the action potential when it reaches the end of the axon, then a simpler approach is to include a time delay in the coupling term. In this case, the general coupling term becomes $f_{ij}(x_i(t), x_j(t - \tau_{ij}))$, where $\tau_{ij} > 0$ represents the time taken for the action potential to propagate along the axon connecting neuron j (the presynaptic neuron) to neuron i (the postsynaptic neuron). The above assumes that the axon of neuron j connects on or close to the cell body of neuron i . Some cells may have synapses or gap junctions on dendrites far from the cell body. In this case, there can also be a delay associated with propagation of the action potential along the dendrite. This will introduce an additional time

delay, viz., $f_{ij}(x_i(t - \tau_{ij}^d), x_j(t - \tau_{ij}^d - \tau_{ij}^a))$, where τ_{ij}^a and τ_{ij}^d represent the time delays due to the propagation of the action potential along the axon and dendrite, respectively. Another delay can occur in the transmission of the electrical signal across the synapse. That is, once the action potential from neuron j reaches the synapse, there is some time before an action potential is initiated in neuron i . A common way to model this is to augment the model equations above by equations modelling the chemical kinetics of the synapse. Alternatively, this can be incorporated by increasing the delay τ_{ij} .

A prototype biological model is the following setup in Campbell and Kobelevskiy (2012) for a network of two neurons:

$$\begin{aligned}\dot{v}_1(t) &= -g_{Ca}m_\infty(v_1(t)) - g_Kw_1(t)(v_1(t) - v_K) \\ &\quad - g_L(v_1(t) - v_L) + I + g_{syn}s(v_2(t - \tau)) \\ &\quad \times (v_1(t) - E_{syn}) \\ \dot{w}_1(t) &= \phi\lambda(v_1(t)) \times (w_1 - w_\infty(v_1(t))) \\ \dot{v}_2(t) &= -g_{Ca}m_\infty(v_2(t)) - g_Kw_2(t)(v_2(t) - v_K) \\ &\quad - g_L(v_2(t) - v_L) + I + g_{syn}s(v_1(t - \tau)) \\ &\quad \times (v_2(t) - E_{syn}) \\ \dot{w}_2(t) &= \phi\lambda(v_2(t)) \times (w_2 - w_\infty(v_2(t)))\end{aligned}\tag{1}$$

Here each neuron is modeled by the Morris-Lecar model, and the neurons are joined with delayed synaptic coupling, with delay τ , coupling strength, g_{syn} . The functions $m_\infty(v)$, $w_\infty(v)$, and $s(v)$ are sigmoidal (specifically, hyperbolic tangents), while $\lambda(v)$ is the reciprocal of a normal distribution (specifically, a hyperbolic cosine). When uncoupled, the individual neurons can be in one of two states depending on the size of the input current I . If I is sufficiently small, the neuron is quiescent, i.e., v_j and w_j are constant in time. If I is large enough (greater than rheobase), the neuron is spiking, i.e., v_j and w_j vary periodically in time.

Another example, referred as a delayed additive or Grossberg-Hopfield network, is given by the model:

$$Cu'_i(t) = -\frac{1}{R}u_i(t) + \sum_{j=1}^n \times \frac{1}{R_{ij}}f_j(u_j(t-\tau_j)). \quad (2)$$

This describes an artificial neural network consisting of electronic neurons with voltages u_i and input impedance described by a combination of a resistor R and a capacitor C interconnected through a matrix of resistors (R_{ij}). Scaling time by the relaxation time, RC , of the individual neurons, shows that an important parameter in determining the dynamics and the computational performance of the network is the relative delay size $r_j = \tau_j/(RC)$. In particular, designing a network so that the individual neurons operate more quickly will increase this relative size of the delay. This model is also used in a biological context to study networks of spiking neurons, i.e., neurons that are intrinsically oscillating. In this context, it is either called a *firing rate* model, in which case u_i is interpreted as the firing rate (frequency of spiking) of the i th neuron (Dayan and Abbott 2001), or a *neural activity* model, in which case u_i is interpreted as the synaptic conductance of the i th neuron averaged over one period of spiking (Ermentrout 1994). Ermentrout (1994) shows how, under certain assumptions and with no time delays, the model (2) can be derived from a model similar to (1).

We have focused here on models for networks in the brain. Time delays are also important in neural networks in the peripheral nervous systems, for example, in the balance control system (Cabrera and Patzwelt 2013).

Mathematical Background and Tools for Analysis

Given a model such as (1) or (2), one would like to determine how the behavior of the network evolves in time, for a particular initial state of the network. In mathematical terms, this means solving an initial value problem for the system of differential equations that defines the model. For an ordinary differential equation model, the initial state is a point, and the solution describes how this point evolves in time in the (finite-dimensional)

state space. Hence it defines a finite-dimensional dynamical system. For a delay differential equation system, the initial state is a function which specifies the values of the variables from the delay time up to the present. For example, for Eq. (2) an initial condition is

$$u_i(t) = \phi_i(t), \quad -\tau \leq t \leq 0$$

where the ϕ_i are known functions. The solution of the initial value problem describes how this initial state evolves in time in an (infinite-dimensional) space of functions. Hence this defines an infinite-dimensional dynamical system. Despite the fundamental differences between finite-dimensional and infinite-dimensional systems, many of the tools used to study the dynamical behavior of ordinary differential equations may be extended to delay differential equations, as summarized in the fairly accessible books of Kolmanovskii and Nosov (1986), Smith (2011), and Stépán (1989). For complete accounts of the theory of delay differential equations, we refer the reader to the books of Hale and Verduyn Lunel (1993) and Diekmann et al. (1995).

Since the initial value problem described above cannot in general be solved in a closed form, a common starting point is to describe the constant (equilibrium) solutions of the system. One then considers the **stability** of these equilibrium solutions. This will give at least a partial picture of the long-term behavior of the network.

For models such as (1) and (2), the equilibrium solutions are the same as the system with no delay (i.e., the ODE system found by setting $\tau = 0$ or $\tau_i = 0$ for all i). They are found by solving the set of algebraic equations determined by the right-hand sides of the differential equations. The equilibrium solutions may, however, change their stability due to the presence of the delay. This delay-induced instability is a common phenomenon, and periodic solutions may bifurcate from these equilibrium solutions when model parameters, especially the time delay, are varied near certain critical values. Detecting these critical values is more technically involved. It requires describing the roots of the characteristic equation, which is a complex transcendental equation. An example is

the Hopf bifurcation (Kazarinoff et al. 1978), where a family of periodic solutions emerges due to the change of stability of the equilibrium solution. In this case, the critical parameter value corresponds to the characteristic equation having a pair of purely imaginary roots. The Hopf bifurcation theorem for delay differential equations (Hale and Verduyn Lunel 1993; Kuang 1993; Smith 2011) determines whether a Hopf bifurcation occurs at such a critical value. Various approaches have been developed for determining the bifurcation direction (subcritical or supercritical) and stability of the resulting periodic orbits (Das and Chatterjee 2002; Erneux 2009; Faria and Magalhães 1995). For an in-depth account of the bifurcation analysis of delay differential equations, see the recent monograph by Guo and Wu (2013). These approaches have been implemented both numerically (Gilsinn 2008; Aboud et al. 1988) and using symbolic algebra systems (Campbell et al. 2006; Campbell 2008; Qesmi et al. 2006).

There are two basic numerical tools which can aid in the study of delayed neural networks: numerical simulation and numerical bifurcation analysis. In numerical simulation, one attempts to determine an approximate solution of a differential equation corresponding to a given initial state. A key issue in numerical integration of delay differential equations is keeping track of the past history of the solution. Both fixed stepsize (Ermentrout 2002) and variable stepsize (Shampine and Thompson 2001) methods have been implemented. In numerical bifurcation analysis, one attempts to determine how the existence and stability of equilibrium points and periodic orbits vary with one or more parameters. To accomplish this, one must bring together tools for finding and approximating equilibrium and periodic solutions of delay differential equations with tools for analyzing characteristic equations (Breda et al. 2004; Engelborghs et al. 2002; Olgac and Sipahi 2002; Szalai et al. 2006).

Creation, Death, and Global Continuation of Oscillations

As discussed above, time delays can be associated with oscillations created by a Hopf bifurcation.

This is sometimes referred to as a *delay-induced oscillation*. One of the simplest examples of this is the following model for recurrent inhibition due to Plant (1981):

$$\begin{aligned}\dot{v}(t) &= v(t) - \frac{1}{3}v^3(t) - w(t) + c(v(t - \tau) - v_0) \\ \dot{w}(t) &= \rho(v(t) + a - bw(t)).\end{aligned}$$

This is a Fitzhugh-Nagumo model neuron with a delayed term which represents recurrent feedback.

In a neural network, the structure of the network can be important for determining if delay-induced oscillations can occur. As noted in (Bélair et al. 1996), for a neural model of the form (2), an important necessary condition for the occurrence of this phenomenon is the presence of frustration, that is, a directed pathway from a neuron to itself such that the product of the connection weights along the path is negative. By contrast, in some network structures, delay does not alter the asymptotic behavior of the system. A globally asymptotically stable contractive network is one example. Cooperative irreducible networks is another. An irreducible network is one in which there is a directed path connecting any pair of neurons. It is referred to as cooperative when, possibly after a change of variables, all interactions are excitatory. Such systems, with or without delay, generate an eventually strongly monotone semiflow, so that the asymptotic behavior of the network with delay is essentially the same as that of the corresponding network without delay (Smith 1995).

Not only can time delays *create* oscillations, but in systems where the uncoupled neurons are oscillating, delays in the coupling can *destroy* the oscillations. This phenomenon, usually called **oscillator death** or **amplitude death**, was first noted by Ramana Reddy et al. (1998), in their analysis of a simple oscillator model with gap junctional coupling.

Much of the existing work on the creation and death of oscillations has focused on the bifurcation near a critical delay or other parameter value. How these oscillations are globally continued when the parameter is far away from the critical

value is a very challenging but an important component of the global dynamics of such a network. Technical tools including the global Hopf bifurcation theory, the discrete Lyapunov functional, and some geometric arguments have been inspired by and applied to this global dynamics issue (Guo and Wu 2013).

Multistability

Incorporating a time lag τ into even a simple neural circuit with feedback yields a scalar delay differential equation $u'(t) = -\beta u(t) + wf(u(t - \tau))$ that defines a semiflow on the infinite-dimensional phase space $C = C([- \tau, 0]; \mathbb{R})$ of continuous functions on the initial interval $[- \tau, 0]$. It has been shown that a network of neurons with delayed signal transmission is capable of storing and retrieving spatiotemporal patterns (Herz 1996; Herz et al. 1989), but the capacity of such a network in the aforementioned studies still relies heavily on the size of the networks and the variable delays associated with different synaptic connections. In particular, if $f' > 0$ (a strictly increasing signal function) and $f(0) = 0$ (normalization), then trajectories of such a network generically converge to a set of two stable equilibria (if $w > 0$, positive feedback, see Krisztin et al. (1999)) or a slowly oscillating periodic solution (if $w < 0$, negative feedback, see Mackey and Glass (1977); Marcus and Westervelt (1989); Walther (1995); Mallet-Paret and Nussbaum (1989)). The simplicity of dynamics limits the application of such a network as an associative memory device – the memory capacity is too low. Additional neural signal processing features must be further incorporated into the model in order for a small network with delay to possess a large number of stable attractors. Such features as firing and the existence of an absolute refractory period are reflected in the well-known Hodgkin-Huxley model (Hodgkin and Huxley 1952), and Foss et al. (1996) showed that neural recurrent inhibitory delayed loops based on the Hodgkin-Huxley model (Hodgkin and Huxley 1952) can indeed exhibit the coexistence (multistability) of three stable equilibria. Ma and Wu (2007, 2010) and Zhou et al. (2012) showed

that the phenomenological spiking model with two neurons, incorporating a firing process and an absolute refractory period, can generate a large number of asymptotically stable periodic solutions with predictable patterns of oscillations.

Time Delay and Network Symmetry

In a network of identical neurons of the form (2) and in the absence of synaptic delays, the asymptotic behaviors of the network can be characterized by the convergence to the set of synchronized equilibria, i.e., equilibria $u_i = u^*$, $\forall i$. Delay-induced instability, however, can give rise to stable phase-locked oscillations and other asynchronous behaviors. The type of behavior is determined by the network topology (Krawcewicz and Wu 1999; Wang and Campbell 2017). In networks of identical, inherently oscillatory neurons, such as given by Eq. (1), multiple different phase-locked states can exist. These states are often called clustered solutions as the neurons are grouped into clusters. Neurons within a cluster are synchronized (phase-locked with zero-phase lag), while neurons between clusters are phase-locked with nonzero-phase lag. The presence of time delay can stabilize otherwise unstable phase-locked solutions (Campbell and Koelevskiy 2012; Dahms et al. 2012; Orosz 2014).

Other Effects of Time Delay

Other issues related to the dynamic behaviors of networks with delay have also been widely considered. Below we describe a few important phenomena observed in networks with delay.

- *Delay-induced chaotic oscillations:* It should be emphasized that delay-induced oscillation need not be periodic and even a two-neuron network can provide a tractable prototype for the study of delay-induced chaos in neural networks (Gilli 1993).
- *Delay-induced change of the domain of attraction:* Even for a cooperative irreducible system whose quasiconvergence is guaranteed, delay may affect the shape and structure of the basins of attraction of equilibria which has significant

impact on its application to content-addressable memory (Pakdaman et al. 1998).

- *Delay-induced transient oscillations*: All the phenomena described above are related to the influence of delay on the long-term behaviors of the system. It should be noted that the delay also affects the transient behavior of networks. As discussed in Pakdaman (2013), for some neural networks, delay may lead to long-lasting transient oscillations whose duration increases exponentially with the delay.

Summary and Implications

In summary, in the study of the effect of signal delays on the network dynamics, an important issue is how signal delays change the stability of equilibria, causing nonlinear oscillations and inducing periodic solutions. While the existence of periodic solutions creates some problems in neural network applications such as content-addressable memory, periodic sequences of neural impulses are the fundamental means of communication in the brain (Buzsa'ki, Buzsáki 2006) and have been investigated in the context of epileptic seizures (Yang and Robinson 2017). Understanding how oscillations are created, destroyed, and modulated is of vital importance in understanding brain function and disfunction. The questions how neural networks can sustain highly periodic activity for a long period of time and what makes them fail under certain conditions are thus of vital interest (Mu"ller and Reinhart 1990).

Time-Frequency Analysis of Analog Neural Signals

Michael X. Cohen

Donders Centre for Neuroscience, Radboud
University Medical Center, Nijmegen,
Netherlands

Definition

Time-frequency analysis is a signal processing method that involves extracting frequency-specific information from temporally localized windows of a signal. Time-frequency analysis is most useful for interpreting signals that are non-stationary, meaning that the spectral characteristics change over time.

Detailed Description

Why Spectral Analysis?

Population-level neural activity, as reflected by the local field potential and electroencephalogram, often exhibits rhythmic temporal patterns with characteristic frequencies, for example, at 10 Hz (“alpha”) or 40 Hz (“gamma”). These rhythmic patterns are called neural oscillations and have been linked to myriad perceptual, cognitive, and motor phenomena (Buzsáki 2006). Careful inspection of rhythmic neural time series suggests that these rhythms are not purely sinusoidal (Cole and Voytek 2017; Jones 2016) yet are sinusoidal enough to justify analysis methods that use sine waves as basis functions, such as the Fourier transform (Cohen 2014).

Spectral Analysis for Stationary Signals

The basic spectral analysis method is the Fourier transform. The Fourier transform involves computing the dot product (a measure of similarity that is also used to compute the correlation coefficient) between the signal and a series of sine waves at a range of frequencies. The more the signal “looks like” the sine wave, the larger the dot product between them. The squared dot

product is termed power and, when plotted over a range of sine wave frequencies, produces the power spectrum that is used to identify rhythmic activity.

Neural time series data (like many other biological and nonbiological signals) often exhibit a decrease in power with increasing frequency, a phenomenon known as “1/f” and implicated in scale-free dynamics reminiscent of fractal-like behavior often observed in nature (Hardstone et al. 2012). Positive deviations from the 1/f – “bumps” in the spectrum – are the spectral manifestations of characteristic frequencies and are taken as evidence of neural oscillations.

Time-Frequency Analysis for Nonstationary Signals

The primary disadvantage of the Fourier transform is that the power spectra it reveals are easily interpretable only for stationary signals, meaning that the features of the signal remain constant over time. Time-varying fluctuations in amplitude, variance, and frequency are not readily visible in power spectra. On the other hand, it is precisely these fluctuations that neuroscientists are interested in studying (e.g., changes in neural activity during stimulus processing or motor planning).

Fortunately, rhythmic nonstationary signals can be understood using a class of analysis methods termed time-frequency analyses. The idea is to assess rhythmic activity over short windows of time, typically hundreds of ms to a few seconds. The “windows” are tapering functions that start and end at or close to 0 and peak at 1. Different time-frequency methods utilize windowing in different ways, but in general, either the data or the template sine waves are windowed. The resulting two-dimensional time-frequency plots indicate changes in the signal over both frequency and time. Two common time-frequency analysis methods are the short-time Fourier transform and wavelet convolution.

Data and Experiment Requirements

Application of spectral analysis methods requires signals that are sampled at regular intervals. This is typically the case in electrophysiology and imaging. A strict requirement is that the

frequencies of interest must be less than one-half of the data sampling rate, as described by the Nyquist theorem. This is generally not a limitation for electrophysiology, as sampling rates can be orders of magnitude higher than the highest frequency of interest. However, the Nyquist theorem does have implications for modern imaging methods (e.g., calcium or glutamate imaging, or magnetic resonance-based imaging), in which sampling rates may be in the range of 0.5–120 Hz, while frequencies of interest may be in the same or higher range. For example, a 60 Hz framerate camera used in a two-photon experiment could not measure activity higher than 30 Hz, which is the lower range of gamma-band oscillations.

Temporal filtering methods often produce “edge effects” at sharp transitions in the signal or at edges of a cut signal. Edge effects should be avoided by removing data that contain sharp edges (such features are typically the result of an artifact such as mechanical or electrical interference), and one should be careful that edges are sufficiently far away from the time windows of interest such that the edge effects will subside in the time window of interest. Thus, a second data requirement is to have clean signals that are sufficiently long to separate filter edge effects from true neural effects.

Perhaps the most important requirement is to have a theoretical motivation or set of hypotheses that spectral methods can provide evidence for or against. Spectral decomposition increases the dimensionality of the data and can increase the statistical and interpretational complexity of the research. Without a clear goal of applying spectral methods, the results may be difficult to interpret.

How to Implement Spectral and Time-Frequency Analysis Methods

There are many open-source toolboxes and proprietary software packages for implementing spectral and related data analyses. Three of the commonly used toolboxes in the MATLAB software program include EEGLAB, Fieldtrip, and Chronux.

Because the mathematics and their numerical implementations in computer programs are not extremely difficult, many research groups prefer

to write in-house code for some or all of the data analyses. There are many educational resources in books and online for learning about these techniques, some of which can be found at sincxpress.com.

Interpreting Time-Frequency Results

Neural oscillations often exhibit fluctuations in amplitude and frequency over time, which is why time-frequency methods are commonly applied to test hypotheses about neural oscillations. Transient oscillations manifest as changes in color or grayscale intensity in the time-frequency plane (an informative color bar should be included to facilitate interpretation).

On the other hand, one must be mindful that transient non-oscillatory events may also have a representation in the time-frequency plane, particularly if those transients have a curved waveform that will be captured by a sine wave or wavelet. Thus, the observation of a feature in the time-frequency plane on its own does not provide unambiguous evidence for the presence of a transient oscillation. For this reason, terms like “narrow-band” or “band-limited” have softer connotations than the term “neural oscillation.”

A commonly used rubric for an interpretation of a neural oscillation is that the feature must be restricted to a canonical frequency band, such as delta (1–4 Hz), theta (4–8 Hz), alpha (8–12 Hz), and so on; and it must exist for several cycles at that frequency. Features in the time-frequency plane that span multiple frequency bands or are present for one cycle are generally not considered evidence of neural oscillations.

Equally or perhaps more important for an interpretation of time-frequency results reflecting neural oscillations is a strong theoretical justification or expectation.

Tinnitus, Models

Roland Schaette
University College London, UCL Ear Institute,
London, UK

Definition

Tinnitus, the perception of a sound in the absence of an acoustic stimulus, often develops after hearing loss. Human neuroimaging studies as well as animal models have shown that the phantom auditory sensation is related to altered patterns of spontaneous neuronal activity in the central auditory system. Computational models have been used to explore which plasticity mechanisms could lead to the development of

neurophysiological correlates of tinnitus. The models show that if a homeostatic plasticity mechanism attempts to stabilize neuronal activity at a certain target level despite the loss of input after hearing loss, the resulting shift in the excitation/inhibition balance can lead to an amplification of spontaneous activity in the central auditory system, thus creating the basis for a tinnitus sensation.

Detailed Description

The phantom auditory sensation of tinnitus is a frequent phenomenon; it is estimated that up to 10% of the population experience chronic tinnitus. The occurrence of tinnitus can be linked to hearing loss in most cases, and even tinnitus patients with normal hearing thresholds show signs of cochlear damage in psychophysical tests and auditory brainstem response measurements (Schaette and McAlpine 2011). Moreover, the pitch of the tinnitus sound is usually matched to frequencies where hearing is impaired.

Tinnitus cannot be abolished by sectioning the auditory nerve, suggesting that the generator of the phantom sound is located in the brain itself. Human neuroimaging studies and animal models have shown that tinnitus is correlated with aberrant patterns of spontaneous neuronal activity in the central auditory system. In animals, cochlear damage can lead to increased spontaneous firing rates of neurons in the cochlear nucleus, the inferior colliculus, and the auditory cortex (see Roberts et al. 2010, for a review). However, the plasticity processes and functional mechanisms that are involved in the generation of such neurophysiological correlates of tinnitus have not been pinpointed yet. To address this open question, computational modeling has been used to study how hearing loss affects activity patterns in the auditory system, which plasticity mechanisms might be activated, and how spontaneous activity is altered in the process. The models therefore provide an interpretational framework for the diverse sets of data from human and animal studies on tinnitus and allow the identification of candidate mechanisms for tinnitus development

by comparing their predictions to experimental data. So far, three main mechanisms have been explored in computational modeling studies of tinnitus: lateral inhibition (Gerken 1996; Bruce et al. 2003), homeostatic plasticity (Schaette and Kempter 2006, 2009; Chrostowski et al. 2011; Schaette and McAlpine 2011), and gain adaptation (Parra and Pearlmutter 2007; Norena 2011). All three mechanisms are ubiquitous in sensory pathways and have been observed in a variety of processing stages of the auditory system.

Lateral inhibition, e.g., inhibition between neurons in the auditory pathway with characteristic frequencies that are close, but not identical, can enhance the activity difference between neurons with high and low levels of activity in a neuronal network. Noise-induced hearing loss can create such an activity difference, as it reduces the spontaneous activity of auditory nerve fibers predominantly in the high-frequency range. When the resulting spontaneous activity pattern with a drop in activity toward the hearing loss region is processed by a neuronal network with lateral inhibition, the neurons just below and at the edge receive less lateral inhibition than their counterparts at lower frequencies, and the neurons just above the edge receive more lateral inhibition. As a consequence, the edge in the activity profile is amplified, leading to a peak in the profile of spontaneous activity. When this activity peak is erroneously interpreted as sound-evoked activity by higher stages of the auditory system, a tinnitus sensation could result (Gerken 1996). However, the resulting tinnitus pitch predictions are systematically too low, as lateral inhibition models generally predict tinnitus pitch to be at the audiogram edge instead of in the region of hearing loss (Schaette and Kempter 2009).

Homeostatic plasticity is a plasticity mechanism that stabilizes the mean activity of neurons on time scales of hours to days (Turrigiano 1999). Several models have explored how this mechanism could contribute to the development of a neural correlate of tinnitus after hearing loss, either in the brainstem (Schaette and Kempter 2006, 2009; Schaette and McAlpine 2011) or in the auditory cortex (Chrostowski et al. 2011):

Hearing loss reduces AN activity with a concomitant reduction in excitatory drive to the central auditory system (Fig. 1, left panels). In order to stabilize mean neuronal activity, homeostatic plasticity then increases excitation and decreases inhibition. The resulting shift in the excitation/inhibition balance increases the overall gain of the neuronal circuits downstream of the AN, which can restore average neuronal activity to normal levels. However, as neurons become more excitable that way, even uncorrelated spontaneous inputs can be amplified, causing an increase of spontaneous firing rates (Fig. 1, right panels). The model thus suggests that tinnitus could be an unwanted side effect of a stabilization of neuronal activity levels in the central auditory system after hearing loss. When the model is applied to audiograms of tinnitus patients with noise-induced hearing loss, the greatest increases in spontaneous firing rates are seen in the region of hearing loss, and tinnitus pitch predictions based on these spontaneous are consistent with observed pitch (Schaette and Kempter 2009).

Gain adaptation is a central feature of sensory processing, as it enables sensory systems to cope with input signals with a wide dynamic range. When gain adaptation is implemented in an abstract model through a running average of input activity that serves as a normalization factor, neural activity in frequency channels that receive little input, e.g., because of hearing loss, is amplified, which then also causes an amplification of spontaneous activity (Parra and Pearlmutter 2007). Gain adaptation models of tinnitus generation have been further explored by Norena (2011), who studied their relation to neural coding efficiency and stabilization of a certain level of mean activity. For long time scales of hours to days, gain adaptation can be regarded as functionally equivalent to homeostatic plasticity, and gain adaptation models also predict tinnitus to be in the region of hearing loss.

Computational modeling has contributed a functional perspective to the study of tinnitus, suggesting that very basic mechanisms like homeostatic plasticity could play a key role in

Tinnitus, Models, Fig. 1 Schematic illustration of homeostatic plasticity models, based on results from Schaette and Kempter 2009. The “knobs” represent the effective response gain of neurons in the central auditory system, determined by the strength of excitatory and inhibitory synapses. Before homeostatic plasticity (*left*), noise-induced hearing loss (e.g., audiogram in the *top panel*) has reduced mean and spontaneous activity of central auditory

neurons with high characteristic frequencies (*bottom panels*). After homeostatic plasticity (*right*), the response gain has been increased in the high-frequency range to restore mean neuronal activity back to the target level. However, due to the increased gain, spontaneously active inputs are amplified, causing an increase in spontaneous firing rates in the region of hearing loss

the development of neural correlates of tinnitus after hearing loss. Computational models of tinnitus have helped to advance theories of tinnitus development and to inspire new experimental investigations.

Topographic Independent Component Analysis

Aapo Hyvärinen

Department of Computer Science, University of Helsinki, Helsinki, Finland

Definition

Independent component analysis of images provides a probabilistic theory on the receptive fields of simple cells in the primary visual cortex (V1). Topographic ICA extends this to a model of the spatial arrangement (columnar structure) of simple cells, as well as their pooling into complex cells. The components (simple cell outputs) are assumed to have statistical dependencies whose strength depends on the distance of the cells on the cortical surface. Furthermore, complex cell outputs are constructed by pooling the energies of simple cells which are close to each other. When the model is estimated from natural images, the spatial organization and the complex cell properties learned are qualitatively similar to what has been observed in mammalian V1.

Detailed Description

Limitations of ICA on Images

Independent component analysis of images, as well as topographic ICA, is based on a linear

superposition model of natural image patches. Denoting the grayscale value of a pixel with 2D coordinates x and y by $I(x, y)$, the linear superposition model assumes

$$I(x, y) = \sum_{i=1}^k A_i(x, y) s_i$$

where the A_i are features or basis vectors and the components s_i are the coefficients of the features in the particular image patch being analyzed. Here, k is the number of components, usually taken to be equal to the number of pixels. The vector I is considered a random vector in the sense of taking different values from patch to patch. The components s_i model outputs of simple cells in V1, and the features A_i , or the inverse coefficients that give the s_i as a function of I , model simple cell receptive fields.

In ICA, the coefficients in s_i are assumed to be statistically independent of each other. However, this assumption is just a rough approximation of the real structure of natural images and is clearly violated when ICA is estimated from real image data. In fact, the ICA model does not have enough degrees of freedom to force the estimated components to be strictly independent.

A prominent form of dependencies that remains after ICA is correlation of energies, i.e., of the squares of the components:

$$\text{cov}(s_i^2, s_j^2) > 0$$

where cov means the covariance. An intuitive meaning of such a nonlinear correlation is “simultaneous activation,” i.e., the components tend to have nonzero values at the same time, but the values need not be linearly correlated (see Fig. 1).

Topographic Extension of ICA

In topographic ICA, we use the dependencies of the linear components s_i to further model the statistical structure of natural images. We start by arranging the simple cells spatially on a two-dimensional surface which models the cortical surface. In mathematical terms, such arrangement means that each component s_i modeling a simple

Topographic Independent Component Analysis, Fig. 1 Two signals which are uncorrelated but have energy correlations or “simultaneous activation.” For illustration purposes only, the signals are plotted as time series

cell is associated with a point on a grid on the 2D plane, as illustrated in Fig. 2. Components which are close to each other are allowed to have strong statistical dependencies, in particular energy correlations. To formalize the notion of two cells being close to each other, we define a *neighborhood function* $\pi(i, j)$ so that $\pi(i, j) = 1$ for components which are close to each other on the grid and zero otherwise.

The neighborhood function is further used to define the complex cell pooling so that complex cells pool energies of simple cells inside each set of neighboring simple cells, giving the complex cell outputs as

$$c_i = \sum_{j=1}^k \pi(i, j) s_j^2 \quad (1)$$

This is essentially a classic energy model of complex cells.

To construct a probabilistic model with the desired dependencies, the probability density function of the images is assumed to depend on complex cell outputs only. This leads to the correlation of energies inside neighborhoods.

The estimation of topographic ICA is performed by maximizing the sparsities of the complex cell outputs c_i . This can be compared with ICA estimation, which is performed by maximizing the sparsities of simple cell outputs s_i . In

Topographic Independent Component Analysis, Fig. 2 Illustration of topographic arrangement of components. The components (*black circles*), each modeling a simple cell, are arranged on a two-dimensional grid. Components which are next to each other are statistically dependent, while components far away are (practically) independent. The grid defines a neighborhood for each component, and pooling into complex cells (*gray circles*, only one shown here) happens inside each neighborhood. (Adapted from Hyvärinen et al. 2009)

fact, the model reduces to basic ICA if the neighborhood function is defined to consist of single components, i.e., when $\pi(i, j) = 1$ if and only if $i = j$ and zero otherwise.

Results on Natural Images

Topographic ICA is applied on natural images in essentially the same way as ICA. Typical results are shown in Fig. 3. The features A_i are very similar to those obtained by ICA. While in ICA the ordering of the cells is completely arbitrary, here we see a clear topographic arrangement of the cells. What is particularly striking is that the preferred orientation of the simple cells changes smoothly as a function of the cortical location (i.e., when moving from one simple cell to the neighboring ones). The same applies for other parameters such as the location of the nonzero

Topographic Independent Component Analysis, Fig. 3 The whole set of vectors A_i obtained by topographic independent component analysis, from Hyvärinen et al. (2009). The size of the patches was 32×32 pixels, the number of patches was 50,000, and the PCA dimension was 256. Each *small square* here corresponds to one component s_i or one feature A_i ; only the A_i can be easily visualized, by representing them like image patches in the original image space. The spatial arrangement of the features in this plot is the topographic one originally defined by the model

part of the receptive field, as well as spatial frequency. These continuities are qualitatively very similar to what has been observed in the mammalian primary visual cortex. However, the model is quite abstract, so direct comparisons to neurophysiological quantities must be approached with caution, like in the case of ICA.

One parameter which does not change continuously with respect to topographic location is the spatial phase of the receptive field, which tells, for example, if the receptive field is odd symmetric (like an edge) or even symmetric (like a bar). Precisely because of this lack of continuity, the complex cells learn to pool over simple cells which are otherwise similar but have different phase preferences, and thus, the complex cells learn to be invariant to the phase of the input. Such phase invariance is the hallmark property of complex cells.

Definition

Topographica is a simulator for large-scale neural models, with special support for neurons organized into topographic maps and for modelling activity-dependent development. A typical Topographica model will cover a complete pathway from the sensory periphery to regions in the cortex, modelling at least several square

millimeters of cortical tissue. To make working at this scale practical, Topographica groups neurons into Sheets, which each typically correspond to a large subpopulation of cells organized in two dimensions across the surface of a neural area. Using this abstraction, Topographica can implement a very large variety of possible models with relatively little coding and thus provides a platform for understanding properties that emerge only when large numbers of neurons are interconnected. The Topographica project also provides reusable, general-purpose components for other scientific computing, which can each be used independently from the main simulator.

Detailed Description

A large fraction of the central nervous system of mammals is organized into systematic topographic maps, with nearby neurons sharing some similar properties (reviewed in the Maps entry). Topographic maps can be implemented using many different simulators, such as NEURON or NEST, but other simulators provide little dedicated support for specifying, analyzing, and visualizing topographic maps. Implementing networks that map between different regions can be complex and error prone, because of the coordinate transformations required and the border conditions that occur for maps and connection patterns of different sizes. Providing good support for modelling maps is important, because the maps provide a level of abstraction that makes it feasible to work with very large numbers of neurons and connections on limited computer hardware and with limited amounts of experimental data available for validation. Topographica is designed to make these large-scale simulations practical, to allow progress in understanding systems-level behavior of neural circuits.

General-Purpose Building Blocks

Topographica has a modular, open design in Python, and many of the major components developed in the project are maintained as completely

independent, general-purpose subprojects that can easily be used with other simulators and other scientific software:

- **FeatureMapper:** Measures and plots feature maps (e.g., ocular dominance maps) tuning curves, and receptive fields, for any model of any sensory modality. Works well with Topographica but can be used with any simulator that can accept an input pattern and return a neural response (e.g., an average activity level).
- **ImaGen:** Generates never-ending streams of resolution-independent, hierarchically composable 0D, 1D, and 2D input patterns (e.g., two-dimensional visual images) for any simulator or other software program. Can be used to simulate the sensory experience of an animal, to generate visual stimuli for experiments, and to specify connection patterns or for any other purpose where parameterizable pattern families are needed.
- **Param/ParamTk:** Extends any Python program with user-controllable, range-checked, automatically documented parameters. Because it has no dependencies outside the Python standard library, the Param module can be used freely for any scientific program, to simplify it, to make it easier to use, and to make it more robust against user errors.
- **Lancet:** Runs large numbers of simulations or any other complex or time-consuming programs (in Python or any other language) and collects the output for analysis or display. Lancet is useful for testing sensitivity to parameters or evaluating model options and when combined with IPython Notebook is part of a comprehensive toolchain for doing reproducible research, starting from model specification and culminating in figures to be used in publications.

Simulations in Topographica

Starting with the separately distributed building blocks above, Topographica adds a general-purpose event-driven simulator (capable of

simulating any causal physical system), automatic plotting via the Matplotlib and PIL libraries, a general-purpose graphical user interface (GUI) allowing any simulated system to be visualized and analyzed without requiring GUI-specific code, and specific support for simulating neurons and topographic maps. Topographica includes libraries of commonly used neural modelling primitives (such as response functions, plasticity rules, and connection types). Each of these components is written in pure Python, which can easily be extended and modified by the user, but the most CPU intensive of these components are also available in high-performance C++-optimized multi-threaded (parallel-processing) versions.

Topographica's support for neural simulations is organized around the idea of a Sheet, a two-dimensional population of similar neurons differing by their location and by their individual connection patterns, but not by their overall properties (such as types of connections, extents of connections, synaptic modification rules, etc.). A Topographica model is typically a set of Sheets and Projections between them, where a Projection consists of a large number of neural connections. Figure 1 shows an illustrative but highly simplified Topographica visual-system model, visualized in the GUI interface.

To run a model, input patterns (from ImaGen) are presented to the input Sheets, such as the retina for this visual system model. Each Sheet will then respond after a specified delay, when the input is received through an incoming Projection. Any network of arbitrary complexity can be modelled in this way, with each Sheet having appropriate detail for the modelling task at hand, and any number of Sheets and Projections used to represent a neural region. Unlike other simulators, all parameters and measurements in Topographica are independent of the actual number of neurons simulated in a Sheet in any particular run, making it simple for the user to select dynamically between coarse but fast, or detailed but slow, approximations to the underlying neural system (Bednar et al. 2004). Even more detailed simulations can be performed by using a Topographica Sheet to wrap around calculations performed in an external simulator (Bednar 2009).

Topographica, Fig. 1 Sample Topographica model. This Topographica screenshot shows a simple visual system model made up of four Sheets (Retina, LGNOff, LGNON, and V1), illustrated in the Model Editor (main Topographica window, *top left*). These Sheets are connected by eight projections (in blue, two from Retina to the lateral geniculate nucleus (LGN), two from LGN to primary visual cortex (V1)), and four lateral projections (in yellow, between cells in the LGN and V1). More complicated models can have dozens or hundreds of such Sheets, representing different subpopulations in different laminae. The other windows show analyses from the FeatureMapper package (Orientation Preference and Topographic mapping windows, *top right*; and Position Preference, *bottom middle right*), along with other types of plots

(LGNOFFAfferent projection, *bottom right*; V1 LateralInhibitory projection, *left*; Connection Fields to a V1 Neuron, *bottom middle left*; Fourier transform of Orientation Preference map (*middle left*); Autocorrelation of Orientation Preference (*middle right*); and Activity for each Sheet, *middle right and top left*). The Activity plots also show two ImaGen input patterns (out of the more than 40 types currently available), and the main Topographica window (*top left*) shows how the ParamTk package is used to generate a GUI interface to edit simulation parameters without any neuroscience-specific code. The layout and look of these windows differs between different versions and different platforms, but this general functionality should be available in any version

Obtaining Topographica and Related Packages

Topographica and all of its subpackages are open source community projects with a BSD license, supporting any platform with Python (including Linux, Mac OS X, and Windows). The code is tested nightly on multiple platforms under a continuous integration framework. All versions of files are tracked via the Git distributed version control system, which makes it simple for users to make local modifications while staying up-to-date with changes to the main repository.

Installable packages and all source code are freely available at topographica.org and [ioam.github.io](https://github.com/iaam).

Transcriptional Control Dysfunction, Modeling

Gillian Queisser

Goethe Center for Scientific Computing, Goethe University Frankfurt, Frankfurt am Main, Germany

Definition

Neurons communicate within networks using electrical signals. These signals are processed by single neurons, translating the electrical code into biochemical signals that subsequently reach the cell nucleus, where transcriptional responses are regulated by highly diverse intracellular space- and time-dependent ionic fluxes. Calcium plays an important role in communicating electrical activity in networks – and on the plasma membrane of neurons – to the cell nucleus (Hardingham et al. 1997; Chawla et al. 1998; Dolmetsch et al. 1998; Milner et al. 1998; Bading 2000; West et al. 2002). Through diffusion and reaction with second messengers (Allbritton et al. 1992, Starovasnik et al. 1992; De Koninck and Schulman 1998; Mermelstein et al. 2001, Schmidt et al. 2003) and intricate calcium exchange mechanisms, e.g., mitochondrial (Kirichok et al. 2004; Popov et al. 2005; Chouhan et al. 2010; Dash et al. 2009; Pradhan et al. 2010) and endoplasmic calcium store exchange (De Young and Keizer 1992; Martone et al. 1993; Keizer and Levine 1996; Spacek and Harris 1997; Higgins et al. 2006; Ryglewski et al. 2007; Chakroborty et al. 2009; Gin et al. 2009), calcium signals can propagate from remote synaptic sites to the nucleus, triggering survival-relevant transcriptional responses (Hardingham et al. 1997; Chawla et al. 1998; Dolmetsch et al. 1998). This enables the cell to regulate its morphology and intracellular architecture based on the neuronal electrical activity within the neural network (Muller et al. 2002; Van Aelst and Cline 2004; Hayashi and Majewska 2005; Tada and Sheng 2006; Wittmann et al. 2009).

Topographica Neural Map Simulator

- [Topographica](#)

Detailed Description

Transcriptional responses in neurons are triggered by cellular signals. In order to understand the intricate interplay between many regulatory pathways of ionic signals, interdisciplinary approaches are becoming even more important. Combining experimental methods ranging from electrophysiology to modern imaging techniques, detailed spatial and time-resolved data can be compiled, defining a foundation for rigorous theoretical investigation of the underlying biophysical cellular processes. As an example, we will focus on cellular calcium signaling, as calcium is one of the most prominent ions involved in a wide variety of cellular tasks.

In order to understand the role of the detailed cellular architecture and cellular and organelle morphologies in relaying information to the cell nucleus, detailed three-dimensional models that include spatiotemporal experimental data as well as the three-dimensional architecture of neurons can be employed (Wittmann et al. 2009; Xylouris et al. 2010; Queisser et al. 2011; Queisser and Wittum 2011). Pathological states in which various parameters are affected, e.g., synapse loss in Alzheimer’s disease (Penzes et al. 2011), changes in receptor and channel densities (Stutzmann et al. 2006; Cheung et al. 2008; Goussakov et al. 2010), or morphological alterations can then systematically be simulated and evaluated. With respect to calcium signaling, models need to include the most relevant calcium-controlling cellular components (see Table 1 for a list of some important key regulators).

Modeling three-dimensional and time-dependent neuronal processes requires advanced mathematical and numerical methods. Typically biophysical processes in space and time can be formulated by systems of partial differential equations using continuum mechanics theory (Wittmann et al. 2009; Xylouris et al. 2010; Queisser et al. 2011). Since the model equations describing neuronal signaling on highly complex morphologies cannot be solved with analytical mathematical tools, numerical approaches are needed to solve the underlying partial differential

equations. Combining these methods with morphology reconstruction tools and automated network generators, based on raw microscopy imaging data and anatomical reconstructions of cells (Queisser et al. 2008; Wolf et al. 2013), allows to develop and solve highly detailed models. Thus, models can include the detailed geometry of cells and organelles, which is relevant for investigating cellular structure/function interplay. Systematic simulations of cellular signals, e.g., under varying parameter sets, allow to identify key components in healthy and pathological neuronal states.

Since transcriptional responses at the nucleus are regulated by the signal that invades the nucleus, it becomes necessary to model the signal that “enters” the nucleus through its nuclear pore complexes (Bading 2000; Wittmann et al. 2009; Queisser et al. 2011). Using models that include the components listed in Table 1, one can investigate the effect of spatial cellular reorganization, ranging from changes in the morphology of the cell, changes in synapse numbers, and distributions all the way to variable receptor densities and positions. First simulations show that the cell can finely regulate calcium signals that are involved in transcriptional responses by employing *neuronal plasticity*. Thus, spatial reorganization of the neuronal structure of dendrites, endoplasmic reticulum, or the position of mitochondria show to be critical in relaying signals to the nucleus.

Transcriptional Control Dysfunction, Modeling, Table 1 Relevant cellular components for synapse to nucleus communication

Cellular components	Relevant parameters
Plasma membrane	PMCA _s , NCX, VDCC
Synapses	NMDA, AMPA receptors, enzymatic production of IP ₃
Cytosol	Diffusion/reaction of calcium, IP ₃ , calbindin, calmodulin
Endoplasmic reticulum	IP ₃ receptors, ryanodine receptors, SERCA pumps
Mitochondria	Uni- and antiporters for calcium
Cell nucleus	Nuclear pore complexes, nuclear calcium diffusion

T

Identifying the key players in these transcriptions, relevant pathways have the potential of evaluating ways on how cells can compensate neuropathological degeneration.

Definition

An electroconvulsive transfer function derives from the linearization of an electroconvulsive model about one of its equilibrium points. Such transfer functions determine the characteristics of the frequency content of simulated electroconvulsive activities in response to input noise(s) to the model.

Detailed Description

For a nonlinear system that started in a stable equilibrium state, small amplitude noise will result in the system fluctuating about this equilibrium state. Characteristics of the fluctuations can be well approximated by linearizing the system about its equilibrium state. The spectra of the fluctuations of the linearized system can be expressed in closed-form mathematical formulas. Analytically expressing the spectra of system fluctuations lets us formulate the effects of a given parameter of the system on system fluctuations. In the following, theoretical and practical aspects of linearization of nonlinear electroconvulsive models

are presented using a simple model described in (Jansen and Rit 1995). This model provided the basis of enhanced models developed in the field of epilepsy (see entry ► “Epilepsy, Neural Population Models of”). Readers may find linearization aspects for a family of more complex electrocortical models in Molaee-Ardekani et al. (2007), Steyn-Ross (2002; Wilcocks 2001), and Bojak and Liley (2005) publications.

Transfer Function of a Template Model

The Template Model

The model we chose as a template is that proposed by Jansen and Rit (1995) for the study of visual evoked potentials. This is a simple neuronal population model (see Fig. 1) as it only includes three subpopulations of cells: pyramidal neurons, excitatory neurons, and inhibitory interneurons. The connections between these subpopulations establish the following linked equations:

$$\left(\frac{d^2}{dt^2} + 2a\frac{d}{dt} + a^2\right)y_0(t) = AaS(y_1(t) - y_2(t)) \quad (1)$$

Transfer Function, Electrocortical, Fig. 1 Schematic diagram of the Jansen and Rit model (1995)

$$\left(\frac{d^2}{dt^2} + 2a\frac{d}{dt} + a^2\right)y_1(t) = Aa(p(t) + C_2S(C_1y_1(t))) \quad (2)$$

$$\left(\frac{d^2}{dt^2} + 2b\frac{d}{dt} + b^2\right)y_2(t) = BbC_4S(C_3y_0(t)) \quad (3)$$

where C_X is the strength of connection between subpopulations. A , B are EPSP and IPSP (excitatory/inhibitory postsynaptic potential) average amplitudes, and a , b are EPSP and IPSP rate constants. $p(t)$ is the (sub)cortical input noise. Finally, S is the sigmoid wave-to-pulse function which is expressed as $S(u) = S_{\max}/(1 + e^{(\theta - u)})$. The output signal of the model $y(t)$ is expressed as $y(t) = y_1(t) - y_2(t)$.

Equilibrium State of the Model

To calculate the equilibrium solution of the model, all d/dt and the variance of the input noise p should be set to zero in Eqs. (1)–(3). This yields the following equations:

$$y_0 = AS(y_1 - y_2)/a \quad (4)$$

$$y_1 = A(p + C_2S(C_1y_0))/a \quad (5)$$

$$y_2 = BC_4S(C_3y_0)/b \quad (6)$$

Substituting Eq. (4) in Eqs. (5) and (6) and then expressing $y = y_1 - y_2$ yields the following nonlinear equation that should be solved numerically for y :

$$y = \frac{A}{a}p + \frac{A}{a}C_2S\left(\frac{A}{a}C_1S(y)\right) - \frac{B}{b}C_4S\left(\frac{A}{a}C_3S(y)\right) \quad (7)$$

The equilibrium state of the model can also be found by an iterative method. y_0 can be treated as an independent variable. Then, y_1 and y_2 are estimated as functions of y_0 and they can be used to estimate y_0 . The solution is reached when $|y_0 - \hat{y}_0|$ is minimized.

Another general way to calculate the equilibrium state of a system is to generate time series of

the system variables from initial starting points. The system should not be perturbed by input noise fluctuations so that system variables can settle down in their equilibrium states. There exists a MATLAB[®] toolbox so-called *matcont* for analyzing dynamical systems (Dhooge et al. 2003).

Hereafter, equilibrium values of the model variables are indicated by filled dots (e.g., y_1^*). Figure 2 illustrates the equilibrium solution of the variable y as a function of the mean input firing rate value p .

Linear Stability of the System

For linear stability analysis, we have to linearize the system differential equations and rewrite the system of equations so it contains only first-order derivatives and then calculate the eigenvalues of the corresponding Jacobian matrix evaluated at the equilibrium state. If a system is defined by N first-order differential equations as $\frac{dx}{dt} = f_m(x_1, \dots, x_N)$, then the Jacobian is the matrix $J_{mn} = \left. \frac{\partial f_m}{\partial x_n} \right|_{\text{equilibrium}}$. The stability of an

equilibrium state is determined by the signs of the real parts of the eigenvalues of the Jacobian matrix. A detailed description about the calculation of the Jacobian matrix for two different electrocardiac models can be found in (Molaei-Ardekani 2007; Wilcocks 2001).

If the Jacobian matrix has an eigenvalue with positive real part, then that equilibrium state is unstable. If all the eigenvalues of the Jacobian matrix have negative real part, then that equilibrium state is stable. In the template model $N = 6$ and $x = \{y_0, y_1, y_2, y_0, y_1, y_2\}$ where the dot symbol represents the derivative operator, stable and unstable equilibrium state solutions of the model for the variable y are represented by blue and red lines in Fig. 2, respectively. Two different types of singularities (i.e., Limit Point and Hopf bifurcations, beyond the scope of the present topic) are also presented in Fig. 2.

Transfer Function of the Linearized System

In the following, the system Eqs. (1)–(3) are linearized. For the sake of simplicity, we do not exactly compute the elements of the Jacobian matrix. Instead, we will directly linearize the second-order system equations. Each of the variables of the model is written as its equilibrium value (indicated by filled circle) plus a time-dependent perturbation from its equilibrium value (indicated by a hat mark); e.g., $\varphi(t) = \varphi^* + \hat{\varphi}(t)$.

For the Eq. (1), we will have

$$\begin{aligned} \left(\frac{d^2}{dt^2} + 2a \frac{d}{dt} + a^2 \right) (y_0^* + \hat{y}_0(t)) \\ = Aa(S^* + \hat{S}(t)) \end{aligned} \quad (8)$$

where

$$S^* = S(u)|_{u=y_1^*-y_2^*}$$

$$\hat{S}(t) = \hat{y}_1(t) \frac{dS(u)}{du} \Big|_{u=y_1^*-y_2^*} - \hat{y}_2(t) \frac{dS(u)}{du} \Big|_{u=y_1^*-y_2^*}$$

Since in the equilibrium state the first and second derivative of the constant value y_0^* is zero and $a^2 y_0^* = Aa S^*$, Eq. (8) can be written as

Transfer Function, Electrocardiac, Fig. 2 Equilibrium state solutions of the template model (Jansen and Rit 1995) for the output variable of the model as a function of input mean firing rate. Stable and unstable solutions are presented by blue and red lines, respectively. H and LP symbols indicate Andronov-Hopf and Limit Point bifurcations. Results were obtained using *matcont* MATLAB toolbox (Dhooge et al. 2003). Numbered indicated points are the points about which the model is linearized. They correspond to values of p equal to 60, 400, and 700

$$\begin{aligned} & \left(\frac{d^2}{dt^2} + 2a \frac{d}{dt} + a^2 \right) \hat{y}_0(t) \\ &= Aa(\alpha_1 \hat{y}_1(t) - \alpha_1 \hat{y}_2(t)) \end{aligned} \quad (9)$$

α_1 is a constant value and represents the derivative value of sigmoid function at the equilibrium point:

$$\begin{aligned} \alpha_1 &= \left. \frac{dS(u)}{du} \right|_{u=y_1^*-y_2^*} \\ &= \left. \frac{S_{\max} r \exp(r(\theta - u))}{(\exp(r(\theta - u)) + 1)^2} \right|_{u=y_1^*-y_2^*} \end{aligned} \quad (10)$$

Similarly, Eqs. (2) and (3) are linearized as follows:

$$\begin{aligned} & \left(\frac{d^2}{dt^2} + 2a \frac{d}{dt} + a^2 \right) \hat{y}_1(t) \\ &= Aa(\hat{p}(t) + C_2 C_1 \alpha_2 \hat{y}_0(t)) \end{aligned} \quad (11)$$

$$\begin{aligned} & \left(\frac{d^2}{dt^2} + 2b \frac{d}{dt} + b^2 \right) \hat{y}_2(t) \\ &= BbC_4 C_3 \alpha_3 \hat{y}_0(t) \end{aligned} \quad (12)$$

where $\alpha_2 = \left. \frac{dS(u)}{du} \right|_{u=C_1 y_0^*}$, $\alpha_3 = \left. \frac{dS(u)}{du} \right|_{u=C_3 y_0^*}$

Taking the Fourier transform from Eqs. (8), (11), and (12) yields

$$\begin{aligned} & (-\omega^2 + 2ai\omega + a^2) \tilde{y}_0(\omega) \\ &= Aa(\alpha_1 \tilde{y}_1(\omega) - \alpha_1 \tilde{y}_2(\omega)) \end{aligned} \quad (13)$$

$$\begin{aligned} & (-\omega^2 + 2ai\omega + a^2) \tilde{y}_1(\omega) \\ &= Aa(\tilde{p}(\omega) + C_2 C_1 \alpha_2 \tilde{y}_0(\omega)) \end{aligned} \quad (14)$$

$$\begin{aligned} & (-\omega^2 + 2bi\omega + b^2) \tilde{y}_2(\omega) \\ &= BbC_4 C_3 \alpha_3 \tilde{y}_0(\omega) \end{aligned} \quad (15)$$

where the tilde symbol is used to express the variable in Fourier domain. Substituting $y_0(\omega)$ from Eq. (13) into Eqs. (14) and (15) and then expressing $\tilde{y}(\omega) = \tilde{y}_1(\omega) - \tilde{y}_2(\omega)$ yields the following transfer function $T(\omega)$:

$$\begin{aligned} \tilde{y}(\omega) &= T(\omega) \tilde{p}(\omega) \Rightarrow T(\omega) \\ &= \frac{\tilde{y}_1(\omega) - \tilde{y}_2(\omega)}{\tilde{p}(\omega)} = \frac{AaL_b(\omega)L_a(\omega)}{D(\omega)} \end{aligned} \quad (16)$$

where

$$L_a(\omega) = (i\omega + a)^2, L_b(\omega) = (i\omega + b)^2,$$

$$\begin{aligned} D(\omega) &= L_a(\omega)L_a(\omega)L_g(\omega) \\ &\quad - A^2 a^2 C_1 C_2 \alpha_1 \alpha_2 L_b(\omega) \\ &\quad + AaBbC_3 C_4 \alpha_1 \alpha_3 L_a(\omega) \end{aligned}$$

Roots of the denominator $D(\omega)$ may determine the stability mode of the model. Indeed, another method to evaluate the stability of a system is to obtain the linear transfer function between the input and output signal in the Fourier domain. Locations of the poles in this transfer function may determine if the system is stable or not. In addition, this transfer function characterizes system fluctuations in response to a given input signal.

Comparison of Numerical and Analytical Solutions

The model was numerically simulated to obtain a time series of 100 s. The power spectrum of the simulated time series was compared with the analytical power spectrum. The input-driving noise was a white Gaussian noise $p(t) = \mathcal{N}\left(p, \frac{\delta^2}{\Delta t}\right)$. The standard deviation of the input noise was set to be a function of Δt in order to conserve the energy of the noise signal when using different time step sizes (for model simulations, see (Wilcocks 2001) for more details). Simulations were performed using Euler method where $\Delta t = 0.1$ ms. Numerical power spectrum was obtained by taking Fourier transform (“fft” function in MATLAB) from 10-s signal epochs (i.e., 10×10 s). The power spectrum was multiplied by $\frac{\Delta t}{Nfft \times 1,000}$ to get a dimension of mV/Hz . The analytical power spectrum was obtained by $Y(f) = \delta^2 |T(2\pi f)|^2 / 1000$.

Figure 3 illustrates simulated time series (2 s) and power spectrum of the model (numerical and

Transfer Function, Electrocortical, Fig. 3 (a) Output time series of the Jansen and Rit model when the variance of the input noise is set to 0.1 and the mean value takes here

different values of 60, 400, and 700. (b) Numerical and analytical (*solid black line*) power spectrums corresponding the conditions given in (a)

analytical) for three different mean input firing rates $p = \{60, 400, 700\}$. Analytical and numerical solutions match well especially where the equilibrium state is far from the unstable region (Hopf bifurcation points). Note that the increase of the variance of the input noise can lead to small differences between analytical and numerical solutions (results not shown).

TREES Toolbox: Code for Neuronal Branching

Hermann Cuntz

Ernst Strüngmann Institute (ESI) for Neuroscience in Cooperation with Max Planck Society, Frankfurt am Main, Germany
Institute of Clinical Neuroanatomy, Goethe University, Frankfurt am Main, Germany

Definition

The TREES toolbox is a software package in MATLAB (MathWorks) that provides tools for reconstructing neuronal branching structures from microscopy image stacks and for generating synthetic axonal and dendritic trees. Furthermore, it enables the analysis, visualization, and editing of these trees for which it provides a large set of dedicated MATLAB functions. The TREES toolbox is freely available as open source at www.treestoolbox.org.

Detailed Description

Accurate predictions of neural computation and network connectivity are well known to require detailed morphological representations. In 2010, we launched a freely distributed open-source software package, the TREES toolbox (Cuntz et al.

2010, 2011), written in MATLAB (MathWorks, Natick, MA). This software package introduces a simple general description of neuronal morphology as a graph connecting targets (e.g., synapses) that are distributed in space. The underlying principle is based on the idea that a dendrite connects these targets in a manner to minimize costs for total cable length and conduction times in the tree (Fig. 1a; Cuntz et al. 2007, 2010). The targets thus become nodes in a graph with dendritic segments being the connecting edges (Fig. 1b). The TREES toolbox provides methods for redistributing nodes on the tree and labelling them to provide a unique representation of the tree (Fig. 1c; Cuntz et al. 2010). Diameter values associated with each node may be mapped to a given tree structure to promote “synaptic democracy” (Häusser 2001; Fig. 1d; Cuntz et al. 2007). The resulting synthetic dendrites are indistinguishable from their real counterparts for synthetically generated cortical pyramidal cells, Purkinje cells, fly interneurons, retina starburst amacrine cells (Cuntz et al. 2010), and periglomerular neurons of the olfactory bulb (Cuntz et al. 2012).

Reconstructing Dendrites and Axons

The process of extracting tree structures from 3D microscopy image stacks is often the first step in studying a neural circuit morphologically. This process remains laborious and no fail-safe automated tracing method exists. The reconstruction procedure typically consists of a sequence of image enhancement, automated or manual tracing, and post-editing. The TREES toolbox is equipped with a user interface that enables all these steps (Fig. 2) and can considerably enhance the speed and accuracy of reconstructions.

Generation of Synthetic Circuits

Generating synthetic branching structures, such as axonal and dendritic trees, also involves a sequence of steps: (1) analyzing branching statistics of real trees, (2) defining a geometric or statistical description of target distributions,

a Minimum spanning trees**b Synthetic tree****c Unique representation****d Refined synthetic tree****TREES Toolbox: Code for Neuronal Branching,**

Fig. 1 Representation of a dendritic tree in the TREES toolbox. **(a)** Targets (*orange dots*) are connected to a dendritic root (*black dot*) to form a tree by minimizing cable length and conduction times within the tree. Four trees are shown connecting the same targets using a different balance between the two costs. **(b)** The result is a graph connecting the targets with edges corresponding to dendritic segments. **(c)** A unique representation of the tree with

equal spacing between nodes (here: large spacing for illustrative purposes) and node labels that conserve the sub-tree structure. **(d)** Diameter values are mapped onto the tree to optimize synaptic democracy (i.e., to equalize the current transfer to the root) and spatial jitter is added to better reproduce biological trees that meander in order to grow through the dense nervous tissue

(3) detailing of the growth process, and then (4) post-editing such as pruning, diameter mapping, and more. The resulting synthetic dendrites are then subjected to a comparison with the real dendrites and the procedure is calibrated to obtain a good match (Fig. 3).

Brief Overview of the TREES Toolbox Functions

Since most of the applications can be divided into recurring modules used in a sequential manner, the TREES toolbox provides many small modular functions to handle neuronal trees. These

individual functions can then easily be recombined to form sophisticated yet comprehensible code. Functions relating to topological features (e.g., branch order or number of termination points) are, for example, separated from those relating to metric features (e.g., segment lengths or diameters). These simple features can then be combined using meta-functions (e.g., that sum up any feature along the path of a tree). A wide variety of traditional measures are available in such a way within one line of code. Editing functions exist at the level of single or groups of nodes but also at the level of entire trees or groups of trees within a network. Concatenating, morphing, resampling, or smoothing is implemented using dedicated MATLAB

The TREES toolbox user interface

TREES Toolbox: Code for Neuronal Branching, Fig. 2 The TREES toolbox user interface. A screenshot of the graphical user interface, which enables the tracing of trees while navigating 3D fluorescent image stacks of a neuron (Here from the medial superior olive, Courtesy of

Philipp Rautenberg et al. (2009)). In the user interface, a user can also easily explore the functions provided with the TREES toolbox. The control panels are indicated with orange shading

functions. Branching as well as electrotonic features can easily be mapped as colors onto cylinder-based neuronal tree models, as morphometric transforms, in density plots or different contours and tree surrounding hulls directly in MATLAB. The resulting OpenGL graphic handles can then be modified at the command line or in the user interface. Neural circuits can further be exported to Blender (<http://www.blender.org/>) or to the Persistence of Vision Raytracer, POV-Ray (<http://www.povray.org/>), for further graphical refinement (Fig. 4). Also, while many electrotonic features are available directly in the TREES toolbox, neural circuits prepared in that environment can be exported to NEURON (Hines and Carnevale 1997) directly for sophisticated compartmental modelling studies.

documentation and demonstration movies are provided on the same website and a developer's website is available at <https://code.google.com/p/treestoolbox>.

Cross-References and Compatibility

Neuronal morphologies in the TREES toolbox can easily be exported to tools for compartmental modelling such as ► “NEURON Simulation Environment” (Hines and Carnevale 1997), ► “GENESIS, the General Neural Simulation System” (Bower and Beeman 1998) and ► “neuroConstruct” (Gleeson et al. 2007). Export functions to ► “NeuroML” (Gleeson et al. 2010) are also available.

Availability and Links

The TREES toolbox is freely available as open source at www.treestoolbox.org. An extensive

Definition

The old paradigm considering brain function solely relying on communication between the pre- and the postsynaptic neuronal compartments has been altered in recent years by the addition of glial cells and in particular astrocytes, as integral actors of this communication process. The close association of astrocytes with presynaptic terminals and postsynaptic spines generates a complex interconnected hub referred to as the *tripartite*

synapses in which astrocytes ensheath the synapses, thereby providing an additional level of complexity to classical synaptic communication (Volterra et al. 2002). Such interaction involves a complex and multifaceted bidirectional communication between astrocytes and pre- and postsynaptic components. A number of computational models have been developed throughout the years to help shed some light on the mechanisms that take place in tripartite synapses and regulate synaptic potency, synaptic plasticity, and consequently learning and memory.

Detailed Description

An action potential reaching the presynaptic terminal of a tripartite glutamatergic synapse triggers a long series of biochemical events. Globally, voltage-dependent calcium channels open, leading to an increase in calcium concentration in the presynaptic terminal; this in turn leads to neurotransmitter release in the synaptic cleft, which is sensed by astrocytes via activation of metabotropic glutamate receptors and glutamate transporters expressed on their surface. This results in an astrocytic increase in calcium concentration, which then triggers the release of gliotransmitters, which have been shown to modulate pre- and postsynaptic functions. All these major steps will be described in greater detail in the following sections, with a focus on astrocytic bidirectional communication in glutamatergic tripartite synapses (Fig. 1).

Neuron to Astrocyte Communication

It is now well established that astrocytes express a number of receptors for neurotransmitters and can therefore sense synaptic activity. Among metabotropic glutamate receptors, mGluR3 and mGluR5 are the most abundant. Activation of mGluR3 inhibits the synthesis of cyclic AMP (cAMP), while mGluR5 activation stimulates PLC, increases IP3 production, and leads to Ca^{2+} release from the endoplasmic reticulum (ER). This astrocytic cascade of events has been

described in a detailed yet compact manner in the G-ChI model (De Pittà et al. 2009), originally derived from the Li–Rinzel model (Li and Rinzel 1994), and faithfully replicates calcium oscillations with endogenous IP3 metabolism.

It is important to note that astrocytic increase in calcium concentration may not only be activated by the very same synapse that is regulated by the astrocyte but also by a different stimulus, thereby providing a heterosynaptic modulation (through distant synapses or astrocytic gap junctions). This heterosynaptic type of communication is generally the one that is modeled, as it permits a more direct measurement of astrocytic activation and gliotransmitter release without interference or need from a direct presynaptic stimulation. Astrocytic sensing mechanisms also involve glutamate transporters, especially EAAT1 and EAAT2 (also called GLAST and GLT-1, respectively), which notably impact the amount of neurotransmitter molecules sensed by synaptic receptors (and to a larger extent extrasynaptic receptors).

Astrocyte to Neuron Communication

Limitation of Synaptic Glutamate Availability

Astrocytic glutamate transporters have been shown to influence synaptic functions by reducing glutamate concentration sensed by postsynaptic receptors following neurotransmitter release and spillover (Volterra and Meldolesi 2005). An illustration of the impact of this mechanism was studied in the computational model proposed by Allam (Allam et al. 2012), which provided evidence indicating that GLT-1 is critical at preventing glutamate buildup during neurotransmission, thereby preventing excitotoxicity.

Gliotransmission

Astrocytic modulation of neuronal function is also mediated by astrocytic release of neurotransmitters or *gliotransmitters*. The major gliotransmitters released from astrocytes are glutamate, ATP, and D-serine; the main targets for glutamate are kainate receptors, metabotropic receptors, and NMDA receptors; P2X, P2Y, and A1 receptors for ATP; and NMDA-R for D-serine. For more details on the underlying

Tripartite Synapse (Neuron–Astrocyte Interactions), Conductance Models, Fig. 1 Illustration of the different interactions that take place at a tripartite glutamatergic synapse

mechanisms, the reader is advised to refer to Parpura and P. G. Haydon (2009).

Release of Glial Neurotransmitter

Even though the exact mechanisms by which astrocytes release gliotransmitters are not fully determined, the release of glutamate is believed to follow the same principles as those occurring in presynaptic terminals (i.e., through a calcium-dependent vesicular process), and different computational models have been proposed to describe the release mechanism (Tsodyks and Markram 1997; Bertram et al. 1996).

Activation of NMDA-R

Glutamate released from astrocytes activates presynaptic metabotropic glutamate receptors and NMDA receptors and, in particular, presynaptic NR2B-containing NMDA receptors at the perforant path–granule cell synapses, which increase presynaptic vesicular release (Jourdain et al. 2007). Such evidence is supported by ultrastructural studies showing close proximity between astrocytes and presynaptic NMDA receptors (the extracellular space being comparable in size to the synaptic cleft). Similarly, astrocytic glutamate release has been shown to

activate extrasynaptic NR2B-containing NMDA receptors on the dendrites of CA1 pyramidal cells, triggering slow inward currents. Additionally, the effect of astrocytic glutamate release on NMDA receptors current may be potentiated by co-release of D-serine, an NMDA receptor co-agonist.

Gliotransmitter-Induced Presynaptic mGluR Activation

The mechanisms underlying presynaptic release modulation via activation of presynaptic metabotropic receptors are still controversial. Despite this, astrocytic release of glutamate has been shown to activate presynaptic metabotropic receptors group I (type 1 and 5) (Perea and Araque 2007). Activation of group I mGluRs induces the formation of IP3 which diffuses to the endoplasmic reticulum where it induces, via binding to a specific receptor, the opening of calcium channels. This in turn increases cytosolic calcium concentration, thereby increasing presynaptic residual calcium concentration. To account for these mechanisms, Tewari (Tewari and Majumdar 2012) proposed a modified Li–Rinzel model that simulates the production of IP3 in a glutamate-dependent process.

Activation of Adenosine A1 Receptors

Activation of astrocytes leads to the release of ATP, which, upon its degradation to adenosine, results in activation of presynaptic A1 receptors. A1-Rs activation in turn inhibits presynaptic release through modulation of intracellular calcium concentration via decrease in cyclic AMP concentration, activation of potassium channels, and inactivation of voltage-dependent calcium channels.

Astrocytic Modulation of Presynaptic Calcium-Dependent NT Release

Presynaptic calcium-dependent release mechanisms conceptually consist of two mechanisms: (i) a calcium concentration increase due to voltage-dependent calcium channels, which open following presynaptic depolarization, and (ii) slower calcium processes, which result from either slow entry from other calcium-permeable

pores or through release from intracellular stores. Presynaptic calcium modulation from astrocytic release has been modeled by modulating the basal release probability in the Tsodyks–Markram release model (Tsodyks and Markram 1997), as proposed by De Pittà (De Pittà et al. 2011) or Tewari (Tewari and Majumdar 2012). Another approach, used by Nadkarni (Nadkarni and Jung 2007), has used a linear relation between the increase of Ca^{2+} concentration in the presynaptic terminal and the increase of Ca^{2+} in the astrocyte, which in turn affects presynaptic vesicular dynamics and subsequently neurotransmitter release.

Conclusion

The involvement of astrocytes in synaptic communication and modulation within the tripartite synapse is a relatively new investigation field. Computational models in particular still rely on a relatively small amount of experimental evidence to describe the different complex processes underlying modulation mechanisms, and much more remain to be discovered. Yet as experimental procedures encounter limitations in uncovering the subtleties of the mechanisms involved, modeling and simulation are needed to help experimentalists to ask the critical questions and to shed some light onto these complex and convoluted interactions.

Definition

Locomotor central pattern generator (CPG) in vertebrates is a neural network located in the spinal cord and capable of generating rhythmic neural activities enabling animal's movements in the environment. The locomotor CPG produces the coordinated rhythmic activities of motoneurons driving contractions of the corresponding muscles resulting in the coordinated limb movements underlying locomotion. The two-level architecture of the mammalian locomotor CPG has been proposed from analysis of spontaneous deletions (errors in rhythmic motoneuron activity) and effects of afferent stimulations during fictive locomotor activity evoked in the decerebrate, immobilized cat preparation by continuous brainstem stimulation. The model suggests that the locomotor CPG contains a separate half-center rhythm generator (RG) and a pattern formation

network (PF) controlled by the RG and defining the coordinated rhythmic pattern of motoneuron activity. The two-level model of the locomotor CPG reproduced and suggested an explanation for a number of features of rhythmic locomotor activity observed in cat locomotion, such as the maintenance of the phase of motoneuron activations after spontaneous deletions and afferent stimulations, that would be difficult to explain in the framework of the classical single-level CPG architecture.

Detailed Description

Motivation for the Proposed Two-Level Organization of the Locomotor CPG

Walking in mammals is characterized by alternating rhythmic activity of flexor and extensor muscles controlling movement of each limb and coordinated movements of different limbs. The corresponding coordinated activity of motoneurons, so-called fictive locomotion, can be evoked in vivo in the decerebrate immobilized preparations or in vitro in the isolated spinal cord of neonatal rodents by brainstem electrical stimulation or administration of some pharmacological agents (Edgerton et al. 1976; Shik and Orlovsky 1976; Grillner and Zangger 1979; Kercut and Bagust 1995; Schmidt and Jordan 2000; Whelan et al. 2000; Burke et al. 2001; Noga et al. 2003). The ability of the spinal cord to generate such rhythmic locomotor-like activity without patterned supraspinal or afferent inputs is considered as a strong proof for the existence of neural circuits representing the spinal locomotor central pattern generator (CPG) (Graham Brown 1911; Grillner 1981; Rossignol 1996; Orlovsky et al. 1999). Graham Brown (1914) proposed the first schematic of the CPG, based on interacting flexor and extensor half-centers. This idea was later elaborated by Lundberg and colleagues (Jankowska et al. 1967a, b; Lundberg 1981). According to this schematic, the locomotor oscillations result from reciprocal inhibition between the flexor and extensor half-centers, mediated by the corresponding inhibitory interneurons. The mutual inhibitory interconnections between the

half-centers ensure that only one half-center can be active at a time. Its activity reduces gradually which results in activation of the antagonistic half-center and switching of the locomotor phase. It was suggested that the flexor and extensor half-centers project to and activate flexor and extensor motoneurons, respectively. Thus, the alternating basic pattern of motoneuron activity is defined by the alternating activity in the half-centers. In addition, under normal conditions, this pattern is modulated by a variety of sensory and descending signals (Lundberg 1981). With such a classical half-center CPG architecture, single CPG network controls both the locomotor rhythm and the pattern of motoneuron activity during locomotion.

Two types of experimental studies of fictive locomotion in the decerebrate, immobilized cat have motivated the concept of two-level architecture for the locomotor CPG. The first series of studies focused on investigation of the effects of afferent stimulations on the activity of motoneurons and step-cycle timing (Guertin et al. 1995; Perreault et al. 1995; McCrea 2001; Stecina et al. 2005). These studies revealed that in many cases, afferent stimulation can delay or cause a premature phase switching within the ongoing step cycle without changing the timing of the following step cycles, i.e., without changing the phase of post-stimulation rhythm.

The other important studies focused on the investigation of so-called deletions – spontaneous errors in the rhythmic activity of motoneurons occurring during fictive locomotion (Lafreniere-Roula and McCrea 2005). Deletions are characterized by brief periods of inactivity (missing bursts) occurring simultaneously in multiple synergist motoneuron populations. During deletions, the activity of antagonist motoneuron populations becomes tonic or maintains rhythmic pattern (Lafreniere-Roula and McCrea 2005). The widespread effect of deletions on the activity of multiple motoneuron pools throughout the limb represents strong evidence that they are produced by failures in the operation of some common spinal circuitry, such as the CPG, and are not a result of local perturbations affecting the excitability of particular motoneurons. An analysis of motoneuron activities after deletions revealed that

some deletions, called “resetting deletions,” were accompanied by a shift in the phase of the rhythm reemerging after deletion relative to the pre-deletion rhythm (Lafreniere-Roula and McCrea 2005). However, most of the deletions observed during fictive locomotion were “non-resetting”: they were characterized by maintenance of the phase of locomotor oscillations after deletions. In fact non-resetting deletions occur during fictive locomotion more frequently than the resetting (78% vs. 22%, see Lafreniere-Roula and McCrea 2005). These observations suggest that the internal structure of the CPG can “remember” the locomotor rhythm when motoneuron activity falls silent. Such rhythm and phase maintenance cannot be explained in the framework of the classical single-level CPG organization, in which a single network is responsible for both rhythm generation and motoneuron activation.

To explain the existence of non-resetting deletions and phase maintenance after afferent stimulations observed during fictive locomotion, Rybak et al. (2006a, b) proposed that the locomotor CPG has a two-level organization and contains a separate half-center rhythm generator (RG) responsible for generation of locomotor rhythm and a pattern formation network (PF) that is controlled by the RG and shapes and coordinates the firing patterns of motoneurons. The two-level CPG organization allows a separate control of the locomotor rhythm (at the RG level) and the pattern of motoneuron activity (at the PF level). Consequently, afferent or descending signals or spontaneously occurring perturbations may affect CPG operation at the RG level, altering the locomotor rhythm (producing a phase shift or rhythm resetting), or act at the PF level, altering the pattern of motoneuron activation without general resetting the rhythm, i.e., without changing the locomotor phase after applied or spontaneously occurring perturbation.

Model Description

Model Structure

Figure 1A shows the architecture of the two-level locomotor CPG model. The top level in the model

represents a half-center RG that controls an intermediate PF network, representing the second level of the CPG and coordinating the activities of flexor and extensor motoneuron populations. The RG consists of two populations of excitatory neurons, RG-E and RG-F, with mutual excitatory synaptic connections within and between these populations. The RG-E and RG-F populations receive external tonic excitatory drive (from the “MLR,” representing the brainstem mesencephalic locomotor region) and are mutually inhibited via the Inrg-E and Inrg-F interneuron populations. The neurons in the RG-E and RG-F populations contain the persistent (slow inactivating) sodium current, I_{NaP} , and possess I_{NaP} -dependent pacemaker properties, which, in combination with reciprocal inhibition between the RG-E and RG-F populations, provide their alternating rhythmic activity. The activities of RG-E and RG-F half-centers define the locomotor rhythm and durations of the extensor and flexor phases, respectively. Alternating firing of the RG-E and RG-F populations provides periodic, alternating excitation (in the homonymous phase) and inhibition (in the opposite phase, via Inrg-E and Inrg-F populations, see Fig. 1) of the excitatory PF-E and PF-F populations.

The PF network, containing the excitatory PF-E and PF-F and inhibitory Inpf-E and Inpf-F populations, represents the second level of the two-level CPG. Each of the PF-E and PF-F populations receives the excitatory tonic MLR drive, alternating excitation and inhibition from the corresponding inhibitory RG populations, and reciprocally inhibits the antagonist PF population via the inhibitory interneuron population (Inpf-E and Inpf-F). Alternating activity of the PF-E and PF-F populations projects to the homonymous motoneuron populations (Mn-E and Mn-F) and to the inhibitory Ia interneuron populations (Ia-E and Ia-F), representing a third level of reciprocal inhibition in the system and rhythmically inhibiting antagonistic motoneuron populations during the inactive phase of the step cycle. The model also includes populations of Renshaw cells (R-E and R-F) that receive collateral excitatory inputs from the homonymous motoneuron populations and provide feedback inhibition to

Two-Level Model of Mammalian Locomotor CPG, Fig. 1 Two-level model of the locomotor CPG. (A) Schematic of the model. Populations of spinal interneurons are represented by *spheres*. Populations of motoneurons are represented by *diamonds*. Excitatory and inhibitory synaptic connections between neural populations are shown by *arrows* and *small circles*, respectively. *RG* rhythm generator circuits are outlined by *yellow rectangle*. Symbols *E* extension and *F* flexion in names of populations indicate the locomotor phase in which each population is active during fictive locomotion. See details

in the text. (B1, B2) Examples of locomotor patterns generated by the model. Activity of each population in this and following simulation figures is represented by a *histogram* of average firing frequency (number of spikes per second per neuron, bin = 30 ms). In B1, the RG-E population receives a larger MLR drive than the RG-F population, and the extensor phase is longer than the flexor phase (an extensor-dominated rhythm). In B2, the RG-F population receives a larger drive, and the model generates a flexor-dominated rhythm. (Adapted from Rybak et al. (2006a) with permission)

motoneurons. Depending on the input from the RG and the interactions within the PF network, each PF population is active during a particular phase of the step cycle and produces a phase-specific synchronized activation of the corresponding group of synergist motoneuron pools.

Modeling Single Motoneurons and Interneurons

The detailed mathematical description of the modeled motoneurons and interneurons can be found in the original paper by Rybak et al. (2006a). Briefly, all neurons were modeled in the Hodgkin-Huxley style. Motoneurons had two compartments, soma and dendrite, and were described based on the previous model by Booth

et al. (1997) with additional incorporation of the persistent sodium current (I_{NaP}) in the dendrite compartment. Specifically, the following ionic currents were included into the soma compartment (Booth et al. 1997; Rybak et al. 2006a): fast sodium, I_{Na} ; potassium rectifier, I_K ; calcium-N, I_{CaN} ; calcium-dependent potassium, I_{KCa} ; and leakage, I_L currents. The motoneuron dendrite compartment included the following currents: I_{NaP} , I_{CaN} , I_{CaL} (calcium-L current), I_K , and I_L . All interneurons were simulated using single-compartment models. The neurons of the RG-E, RG-F, PF-E, and PF-F populations contained I_{Na} , I_{NaP} , I_K , and I_L . For simplicity, all other interneurons contained only a minimal set of ionic currents: I_{Na} , I_K , and I_L (for details, see Rybak et al. 2006a).

Modeling Neural Populations

Each functional neuron type was represented by a population of 20 neurons. Connections between the populations were established so that if a population A was assigned to receive an excitatory or inhibitory input from a population B or external drive D, then each neuron of population A received the corresponding excitatory or inhibitory synaptic input from each neuron of population B or from drive D, respectively. The heterogeneity of connections was provided by a random distribution of connection weights between individual neurons. The heterogeneity of neurons within each population was set by a random distribution of leak reversal potentials and initial conditions for values of membrane potential, calcium concentrations (in motoneurons), and channel conductances between neurons (for details, see Rybak et al. 2006a).

Model Performance

Generation of Alternating Flexor-Extensor Activity in the Model

Figure 1B1, B2 shows examples of locomotor rhythm and flexor and extensor motoneuron activity generated by the model. In this figure, the activity of each population is represented by a histogram of average neuron activity (number of spikes in the population per second per neuron). The basic locomotor rhythm is generated by the RG network. The alternating rhythmic bursts of the RG populations (top two traces in Fig. 1B1, B2) define the durations of extensor and flexor phases and hence the locomotor (step-cycle) period. An increase in the MLR excitatory drive to one of the two RG populations reduces the opposite phase duration (see for explanation Rybak et al. 2006a). In Fig. 1B1, the MLR drive to the RG-E population is higher than that to the RG-F population resulting in a longer duration of extensor phase. In Fig. 1B2, a higher drive to the RG-F population results in a flexor phase-dominated rhythm. Only a reduced model was considered, in which the PF network consisted of only two (extensor and flexor) populations reciprocally inhibiting each other. As seen in the

figure, the activity of each PF population closely followed the activity of the corresponding RG population, and the activities of Ia inhibitory interneurons, motoneurons, and Renshaw cells followed the activity of the homonymous (extensor or flexor) PF populations (see the corresponding traces in Fig. 1B1, B2).

Comparison of the Experimental and Modeling Results

The results of simulations were compared with the previous experimental data of Lafreniere-Roula and McCrea (2005), whose investigation focused on deletions, and the data of Guertin et al. (1995) and Stecina et al. (2005) who studied the effects of afferent stimulations. All these data represented simultaneous recordings of electroneurogram activity (ENG) (and intracellular recordings) from motoneurons controlling the major hind limb muscles during MLR-evoked fictive locomotion in the decerebrate, immobilized cat.

Modeling Deletions

Deletions represent brief failures in the alternating rhythmic activity of flexor or extensor motoneurons spontaneously occurring during fictive locomotion. During deletions the activity of multiple agonist motoneuron populations is missing for some time period, while the activity of their antagonists becomes tonic or continues to be rhythmic (Lafreniere-Roula and McCrea 2005). Deletions are classified to be “resetting”, if the phase of post-deletion rhythmic activity changes with respect to the pre-deletion rhythm, or “non-resetting”, if there is no phase shift in the reappearing post-deletion activity. The type of the deletion in the model depends on where in the network the perturbation occurs (is applied during simulation). The onset and offset of such perturbation can occur at arbitrary times (phase) with respect to the locomotor rhythm. Therefore, if these perturbations represent temporary changes at the RG level of the CPG (e.g., in the excitability of one of the RG population), the post-deletion rhythm should be generally phase shifted with respect to the pre-deletion rhythm. In contrast, temporal changes in the excitability of one of the PF populations do not affect the RG and hence should

cause only deletions occurring without phase shift of the post-deletion rhythm. Thus, it can be suggested that resetting deletions are caused by some spontaneous perturbations in excitability of neurons at the RG level of the spinal locomotor CPG, while perturbations at the PF level result in non-resetting deletions.

An example of an experimentally observed resetting deletion is shown in Fig. 2A (Lafreniere-Roula and McCrea 2005). In these records, rhythmic activity of extensors (hip, SmAB, and ankle, MG and LGS) was suppressed, and the activity of flexors (hip (Sart) and ankle (TA)) was prolonged. This behavior was closely reproduced in the model (see Fig. 2B) by applying a brief increase in the excitatory drive to the RG-F population. This increase in the excitatory drive prolonged activity of the RG-F half-center (top trace in Fig. 2B) and substantially inhibited the opposite (RG-E) half-center (second trace in Fig. 2B). The sustained activity of the RG-F population projected to the PF-F population (third trace in Fig. 2B). As a result, the activity of the PF-E (fourth trace) population was completely suppressed which resulted in a deletion of extensor motoneuron activity with a sustained activity of flexor motoneurons (see two bottom traces in Fig. 2B). The vertical dashed lines in the figure indicate the beginning of the expected flexor bursts if the deletion did not occur. In both the experimental and modeled examples, there is an obvious phase shift of the post-deletion rhythm. A similar deletion of extensor motoneuron activity can be produced by temporary reducing (or eliminating) the MLR drive to the extensor side of the RG.

Figure 3A1 shows an example of a non-resetting deletion of flexor activity obtained during fictive locomotion (Lafreniere-Roula and McCrea 2005). The failure of flexor motoneuron activation (hip, Sart, and ankle, EDL) is accompanied by the continuous activity of extensors (hip, SmAB, knee, Quad, and ankle, Plant). The vertical dashed lines indicate the beginning of the expected flexor bursts if the deletion did not occur. This behavior was simulated with the model by applying a temporary increase in the total excitatory drive to the PF-E population (Fig. 3B1). The

Four *upper traces* show ENG recordings from hip (Sart) and ankle (TA) flexors and hip (SmAB) and ankle (MG, LGS) extensors. Two *bottom traces* are intracellular recordings from single Sart and SmAB motoneurons. In this and the following figures, the vertical *dotted lines* are plotted at the intervals representing the average period calculated for the five step-cycle periods preceding the deletions. These *lines* indicate where the onsets of anticipated flexor bursts that would have occurred if there had been no deletion. *Arrows* at the *bottom* indicate the phase

locomotor period (defined by neural activity at the RG level) was unaffected (see two top traces in Fig. 3B1) during and after deletion though there was a failure to excite flexor motoneurons (see second trace from below). This resulted from activities of the PF-E and PF-F populations (see third and fourth traces). As mentioned above, the PF-E population in this simulation received an additional excitation that overcame its inhibition by the Inrg-F and Inpf-F populations (see Fig. 1A) during the flexor phase, which resulted in a sustained activity of the PF-E population. Note that a continuing rhythmic inhibition of the PF-E population by the Inrg-F population resulted in a rhythmic modulation of the sustained activity of extensor motoneurons and a temporal interruption of the PF-E activity and emergence of a brief burst of flexor activity in the PF-F and Mn-F populations. A rhythmic modulation of the sustained activity of extensor motoneurons (Mn-E) during flexor deletion in Fig. 3B1 and the emergence of a flexor burst at the fourth (from the left) vertical dashed line are strikingly

similar to that observed in the extensor ENGs during fictive locomotion (Fig. 3A1).

Figure 3A2 shows an example of a non-resetting deletion of extensor activity during fictive locomotion (Rybak et al. 2006a). In this example, an unknown spontaneous perturbation caused the deletion of activity of extensor motoneurons operating at hip (SmAB) and ankle (GS and Plant) accompanied by a sustained activity of flexor motoneurons (ankle, TA and PerL). The failure of flexor motoneurons to hyperpolarize during this period is illustrated in the intracellular record from a TA motoneuron (Fig. 3A2, bottom trace). The reappearance of extensor ENG activity occurred at the time expected if the deletion did not occur. Note the hyperpolarization of the TA motoneuron when extensor motoneuron activity reappears following the deletion. This behavior was simulated with the model by applying a temporary increase in total excitatory drive to the PF-F population (see Fig. 3B2) and showed a striking similarity to the deletion occurring during fictive locomotion including the weak modulation of flexor activity at the moments of expected extensor activity.

Sometimes, during non-resetting deletions of agonist motoneurons, antagonist motoneurons continue to be rhythmic (Lafreniere-Roula and McCrea 2005). Such example is shown in Fig. 4A where the failure of excitation of extensor motoneurons (hip, SmAB, and ankle, MG and LGS) is accompanied by continuous rhythmic activity of flexor motoneurons (hip, Sart, and ankle, TA and PerL). After deletion, the extensor activity reappears without phase shift, i.e., similar to that during other non-resetting deletions. This behavior could be simulated with the model by a temporary suppression of excitatory drive to the PF-E population (see Fig. 4B). Note that this suppression was decreased with time. Under these conditions, the model reproduced the deletion of activity of extensor motoneurons accompanying by continued bursting activity of the flexor motoneuron population and appearance of extensor bursts of a reduced amplitude after the deletion, which strikingly resembles the experimental data shown in Fig. 4A. Similar to the experimental recordings in Fig. 4A, the locomotor

←

Two-Level Model of Mammalian Locomotor CPG, Fig. 2 (continued) shift of the post-deletion rhythm in respect to the pre-deletion activity. **(B)** Simulation reproducing the deletion shown in A. In this simulation, the MLR drives were adjusted to approximately fit phase durations in experimental recordings shown in A. The deletion of extensor activity was produced by an additional excitatory drive to the RG-F population (illustrated by the horizontal black bar at the top of traces). The deletion episode is highlighted by grey rectangle. Two upper traces show the activities of the RG-F and RG-E populations. The increased total drive to the RG-F population caused a prolongation of the RG-F activity and a delay in the transition to the extensor phase. This produced a corresponding prolongation of the activity of the PF-F (third trace) and Mn-F (fifth trace) populations and a delay in the onset of activity of the PF-E (fourth trace) and Mn-E (third trace from below) populations during the simulated deletion episode. Two bottom traces show changes in the membrane potential of single flexor and extensor motoneurons (*mn-F* and *mn-E*, respectively; action potentials are truncated at -40 mV). As in the case of experimental recordings shown in A, the “perturbation” applied to the RG-F population produced a resetting extensor deletion accompanied by a shift in the phase of the post-deletion rhythm (see arrows at the bottom). (Modified from Rybak et al. (2006a) with permission)

Two-Level Model of Mammalian Locomotor CPG, Fig. 3

Examples of non-resetting deletions with sustained activity of antagonists. (**A1**, **A2**) Two episodes of non-resetting deletions occurred during MLR-evoked fictive locomotion. The *traces* are rectified-integrated recordings from hind limb flexors and extensors. The *vertical dotted lines* indicate where the onsets of flexor (**A1**) or extensor (**A2**) bursts would have occurred if there had been no deletion. It can be seen that the phase of the locomotor rhythm is maintained after deletion in both episodes. In **A1**, the ENG recordings from hip (*Sart*) and ankle (*EDL*) flexors and hip (*SmAB*), knee (*Quad*), and ankle (*MG*, *Plant*) extensors are shown. During two successive flexor deletions, all extensors demonstrate a sustained activity, while all flexors are silent. In **A2**, the ENG recordings are shown from ankle flexors (*TA*, *PerL*) and hip (*SmAB*) and ankle (*GS*, *Plant*) extensors. The *bottom trace* shows an intracellular recording from *TA* motoneuron. The activity

of all extensors is suppressed during the extensor deletion with a sustained activity of flexors. It can be seen that the phase of the locomotor rhythm is maintained after deletions shown in **A1** and **A2**. (**B1**, **B2**) The results of simulations reproducing experimental recordings shown in **A1** and **A2**. In these simulations, the MLR drives were adjusted to fit phase durations in the corresponding experimental data. Two *upper traces* show activities of the RG populations, the *third and fourth traces* demonstrate the activities of the PF-F and PF-E populations. Two *bottom traces* show changes in the membrane potential of single flexor and extensor motoneurons (*mn-F* and *mn-E*, respectively, action potentials truncated at -40 mV). The deletion episodes are highlighted by *grey rectangles*. In the simulation shown in **B1**, a deletion of flexor activity was produced by an additional excitatory drive to the PF-E population (see *horizontal black bar* at the top of traces). Similar to the experimental recordings in **A1**, the phase of the locomotor

period (defined by the RG activity) remained unaffected when flexor motoneuron activity fell out.

Modeling Afferent Stimulations

Although the spinal CPG can operate in the absence of sensory feedback (e.g., during fictive locomotion), afferent activity plays a critical role in adjusting the locomotor pattern to the motor task, environment, and biomechanical characteristics of the limbs and body (Pearson 2004; Rossignol et al. 2006). In this connection, Rybak et al. (2006b) considered the effects of activation of the extensor and flexor afferents using the two-level CPG model. An important point for the modeling effect of afferent stimulation is the demonstration that afferent stimulation can affect (delay or advance) the ongoing phase transition with or without affecting the phase of post-stimulation locomotor rhythm (timing the following cycles) (see details in Rybak et al. 2006b). Briefly, it was suggested that both extensor and flexor afferents access the locomotor spinal CPG at several levels (see Figs. 5 and 8).

Effects of Extensor Afferent Stimulation

Figure 5 shows the schematic of the model used to simulate the effects of extensor afferent (both Ia muscle spindle and Ib tendon organ) stimulation using the two-level locomotor CPG. It was hypothesized that there are separate pathways for extensor afferents to the RG and the PF levels of the CPG via the hypothetical Irg-E and Ipf-E populations, respectively. The synaptic weights of inputs to the PF-E population in the model

(controlling extensor activity at the PF level) are stronger than that to the RG-E population (the extensor half-center of the RG). Accordingly, the model suggests that if sensory stimulation changes the excitability of the RG-E population, it may alter the cycle period. The model also includes monosynaptic excitation of homonymous motoneurons and disynaptic inhibition of antagonists by group Ia afferents. To reflect the presynaptic inhibition of extensor and flexor afferents during locomotor state (Gosgnach et al. 2000; McCrea 2001), the weight of Ia monosynaptic excitation of motoneuron populations in the model has been made low. The model also includes the locomotor-dependent disynaptic excitation of motoneurons (see Angel et al. 2005) that is mediated by the excitatory population Iab-E. During extension (i.e., when the PF-E and Inpf-E populations are active), the Inpf-E population inhibits an additional In-E population, thus removing the In-E inhibition of Iab-E interneurons. This disinhibition permits a phase-dependent disynaptic excitation of extensors by group I extensor afferents (Schomburg and Behrends 1978; McCrea et al. 1995; Angel et al. 1996, 2005). In addition, excitation of Iab-E interneurons from the PF-E population creates rhythmic extensor-phase activity in Iab-E interneurons in the absence of sensory stimulation that was found experimentally (Angel et al. 2005). Thus the Iab-E population also provides a portion of excitation to the extensor motoneurons during locomotion. Nonetheless, the Iab-E population is not considered to be an integral part of the locomotor CPG. This is because this interneuron

Two-Level Model of Mammalian Locomotor CPG, Fig. 3 (continued) rhythm is maintained after deletions. Note that during deletion, the simulated flexor motoneuron (*mn-F*) is hyperpolarized. The extensor motoneuron (*mn-E*) shows phasic modulation in its spiking without hyperpolarization similar to that observed in ENG of extensors (*SmAB*, *Quad*, and *Plant*) in **A1**. In **B2**, the performed simulation reproduces the extensor deletion shown in **A2**. In this simulation, a deletion of extensor activity was produced by an additional temporal excitatory drive to the PF-F population (see *horizontal black bar* at the *top of traces*) providing a prolonged activity of this

population (*third trace*). Similar to the experimental recordings in **A2**, the phase of the locomotor rhythm was maintained after deletion. As in the simulation shown in **B1**, rhythmic activity of the RG-E (*second trace*) and Inrg-E (not shown) populations persisted and provided phasic modulation of Mn-F activity (*fourth trace* from the *bottom*). Note that during deletion, the extensor motoneuron was hyperpolarized, whereas the flexor motoneurons showed phasic modulation without obvious hyperpolarization similar to that in an intracellular recording from TA motoneuron (two *bottom traces* in **A2**) (Modified from Rybak et al. (2006a) with permission)

Two-Level Model of Mammalian Locomotor CPG, Fig. 4 Example of non-resetting deletion with rhythmic activity of antagonist motoneurons. (A) Example of a deletion of extensor activity accompanied by continuing rhythmic activity of flexor motoneurons. The ENG recordings made from hind limb flexors (hip, *Sart*, and ankle, *TA*, *PerL*) and extensors (hip, *SmAB*, and ankle, *MG* and *LGS*) are shown. The bottom trace shows intracellular recording from a flexor (*EDL*) motoneuron that did not generate action potentials during fictive locomotion but shows rhythmic modulation of the membrane potential. Interestingly, the first extensor burst reappearing after deletion has lower amplitude. The vertical dotted lines indicate where the termination of extensor bursts would have occurred if there had been no deletion. They show that the phase of the

locomotor rhythm is maintained after deletion. (B) Simulation results similar to the experimental data shown in panel A. The MLR drives are adjusted to fit the locomotor phases in the experiment. In this simulation, a deletion of flexor activity (highlighted by grey rectangle) was produced by a temporal, gradually decreasing reduction of excitatory drive to the PF-E population (fourth trace), which is illustrated by gradual change in grey-level intensity of the rectangle. Three bottom traces show changes of membrane potentials of single flexor (*mn-F*) and two extensor motoneurons (*mn-E₁* and *mn-E₂*, respectively; action potentials truncated at -40 mV). Similar to the experimental data shown in A, the first burst after the deletion has lower amplitude. Note that during this burst, *mn-E₁* motoneuron is depolarized but did not generate

population does not participate in rhythm generation, and in some locomotor preparations, excitability of Iab-E interneurons is low and disynaptic excitation of motoneurons by group I extensor afferents cannot be evoked (e.g., in low spinal cats, McCrea et al. 1995). A detailed discussion of how group I disynaptic excitation emerges during locomotion and replaces the inhibitory effects evoked at rest is presented elsewhere (Rybak et al. 2006b).

A large body of experimental evidence shows that proprioceptive feedback from extensor afferents results in a strong excitation of extensor motoneurons that contributes to a substantial portion of stance-phase extensor activity in cats during treadmill locomotion (Donelan and Pearson 2004; Rossignol et al. 2006) and in man (Sinkjaer et al. 2000). In reduced preparations, activity in extensor afferents can also control the transition from extension to flexion, regulate the duration of the extensor phase, and entrain the step-cycle period (Guertin et al. 1995; Pearson 2004; Rossignol et al. 2006).

Figure 6A shows the effects of a brief stimulation applied to group I ankle extensor (LGS) afferents during the flexor phase in fictive locomotion preparation. In this example (Guertin et al. 1995), flexor motoneuron activity (ankle, TA) is truncated soon after stimulus onset (black rectangle), and a burst of extensor activity occurs (hip, AB, and knee, Quad). Figure 6B shows a result of modeling the effects of extensor afferent stimulation during flexion which reproduces experimental results shown in Fig. 6A. In this example, a brief stimulation of extensor afferents (see black rectangle at the top of traces) is delivered to the RG-E and PF-E populations (via the Irg-E and Ipf-E populations, respectively, see Fig. 5) during flexion, i.e., when the flexor motoneuron population (Mn-F) is active. During the flexor phase both the RG-E and PF-E populations are inhibited by activity in the flexor half-center (via the Inrg-F

and Inpf-F populations, see Fig. 5). The relatively weak synaptic input from extensor afferents to the Irg-E population cannot overcome the flexion phase-related inhibition of the RG-E population (by the Inrg-F population) and excite it. Thus, the RG activity (first and second traces in Fig. 6B) is unaffected by the afferent stimulation. However, the stronger synaptic weights of the afferent input to the Ipf-E population can evoke a brief excitation of PF-E interneurons, which in turn, (via the Inpf-E population, see Fig. 5) inhibit the PF-F activity (third and fourth traces in Fig. 6B). As a result there is a resetting of the PF activity to extension (without affecting the RG activity) that evokes a brief burst of extensor motoneuron activity (Mn-E) and a corresponding inhibition (cessation of activity) of flexor motoneurons (Mn-F) (see two bottom traces in Fig. 6B). In both the experiment (Fig. 6A) and the model (Fig. 6B), the duration of the evoked extensor activity and the following flexor phase are shortened such that phase shift of the locomotor rhythm does not occur. This is illustrated in Fig. 6A, B by the dashed lines indicating intervals equal to the step-cycle period preceding stimulation and by the arrows at the bottom of the figure. According to the model, the fictive locomotor data in Fig. 6A can be explained by the suggestion that extensor afferent stimulation during flexion produces a temporary resetting to extension at the level of the PF network without affecting the RG level of the CPG and hence, without any change in the timing of the following step cycles.

During real locomotion, extensor group I afferent feedback occurs mainly during the extension phase when Ib afferents are active because of extensor muscle contractions (Prochazka and Gorassini 1998). Figure 7A1, A2 shows the experimental data in which Plant nerve stimulation enhanced and prolonged extensor motoneuron activity (hip, AB, knee, Quad, and ankle, MG). It can be seen that there is a

Two-Level Model of Mammalian Locomotor CPG, Fig. 4 (continued) action potentials, while mn-E₂ generates a reduced burst of activity. As in the experimental

recordings shown in A, the phase of the locomotor rhythm did not change after deletion. (Modified from Rybak et al. (2006a) with permission)

Two-Level Model of Mammalian Locomotor CPG, Fig. 5 Schematic of the spinal cord circuitry with the two-level model locomotor CPG used for simulating the effects of stimulation of extensor group I afferents. The two-level locomotor CPG model (see Fig. 1A) is extended by incorporating additional neural populations Irg-E and Ipf-E (green) that receive group I (Ia and Ib) afferents (shown by green lines) and provide excitatory inputs to the RG-E or PF-E populations, respectively. The Iab-E population mediates disynaptic excitation of extensor motoneurons during the extensor phase of locomotion. See text for details. (Modified from Rybak et al. (2006b) with permission)

shortening of the subsequent flexor phase such that the step-cycle period remained unchanged (see arrows at the bottom of Fig. 7A1). Figure 7B1 shows the results of simulation consistent with the experimental data shown in Fig. 7A1. The stimulation in Fig. 7B1 (shown by black rectangles at the top of the traces) had the same amplitude as in Fig. 6B and produced little effect on the activity of the RG populations and hence did not change the ongoing locomotor rhythm generated by the RG (see first and second traces in Fig. 7B1). The applied stimulation did, however, enhance and prolong the PF-E population activity, thus delaying the switching to the flexion phase at the PF-F level (see third and fourth traces in Fig. 7B1) and enhanced and

Two-Level Model of Mammalian Locomotor CPG, Fig. 6 Effects of extensor afferent stimulation during flexion. (A) Example of stimulation of extensor group I afferents in LGS (1.6 times threshold, T; 20 shocks, 100 Hz, black rectangle) during flexion terminated the ongoing flexor phase (see the activity of TA (ankle flexor)) and produced a premature onset of extension as seen in ENG of the hip (AB) and knee (Quad) extensors. (B) Results of simulation of the experimental data shown in panel A. Small black rectangle at the top of traces shows time and duration of sensory stimulation applied to group I (Ia and Ib) afferents. The MLR drives to the RG-E and RG-F populations are adjusted to fit phase durations in the experiment shown in A. Note that in panel B, similar to A, stimulation resulted in a short extensor burst and a shortened next flexion so that the timing of the following step cycles did not change: i.e., the locomotor rhythm was not reset. The arrows at the bottom show that the locomotor periods before, during, and after application of stimulation are the same. (Adapted from Rybak et al. (2006b) with permission)

prolonged extensor motoneuron firing (see the bottom trace in Fig. 7A1). Because the RG level in the locomotor CPG model was not affected, the subsequent flexion phase was shortened and the step-cycle duration remained unchanged.

Two-Level Model of Mammalian Locomotor CPG, Fig. 7 Effects of group I extensor afferent stimulation during extension. (**A1**, **A2**) Examples of stimulation of extensor group I afferents during MLR-evoked fictive locomotion. In **A1**, stimulation of Plant group I afferents during extension (1.6 T, 20 shocks, 100 Hz) increased the amplitude and duration of extensor motoneuron activity (hip, *AB*, knee, *Quad*, and ankle, *MG*) and shortened the duration of the following flexor phase as seen in *Sart* (hip/knee flexor). In **A2**, an example of electrical stimulation of hip extensor (*Sm*) muscle afferents during extension (2 T, 20 shocks, 100 Hz, from Rybak et al. (2006b), used with permission) is shown. Note that the intensity of stimulation was increased (2 T vs. 1.6 T in **A1**). Similar to the experimental results shown in panel **A1**, stimulation increased the amplitude and duration of ankle extensor motoneuron activity (*MG*). However, in contrast to **A1**,

each flexion phase following the prolonged extension phase was not shortened. Therefore, each stimulus shifted the locomotor rhythm in time, which resulted in an increase in the locomotor period (see arrows at the bottom). (**B1**, **B2**) Examples of modeling the effects of stimulation of the group I extensor afferents during extension shown in **A1** and **A2**, respectively. The drives to the RG-F and RG-E populations are adjusted to fit the corresponding experimental recordings. The applied stimuli are shown as black rectangles at the top of traces. The increased height of the rectangles in panel **B2** compared to **B1** symbolically illustrates the increased stimulation intensity. Note that in **B1**, the low-intensity stimulation did not cause any perturbation in the RG activity (see two upper traces), and, similar to **A1**, the locomotor periods did not change because duration of each flexion phase following the prolonged extension phase was shortened (see equal length arrows

A different experimental example is shown in Fig. 7A2. In this example, stimulation applied to extensor afferents (hip, Sm) evoked enhancement of extensor motoneuron activity similar to the experiment shown in Fig. 7A1; however, the ongoing step-cycle period increased. Each stimulus in Fig. 7A2 enhanced and prolonged extensor (ankle, MG) burst. The following flexor phase had an unchanged duration, and hence, the locomotor rhythm was shifted in time (see arrows at the bottom of the panel). These experimental results are reproduced in simulation shown in Fig. 7B2. In this simulation, the amplitude of stimulation was increased as compared to the simulation shown in Fig. 7B1 (illustrated by the increased height of black rectangles at the top of the traces), while maintaining the same relative weightings to the PF-E and RG-E populations. In contrast to Fig. 7B1, stronger stimulation prolonged the RG-E activity which in turn delayed the transition to flexion at the RG level (see first and second traces in Fig. 7B2). This stimulation also prolonged and enhanced the PF-E activity (see fourth trace in Fig. 7B2). The net effect was an increase and prolongation of extensor motoneuron firing, but there was, however, no compensatory change in the duration of the subsequent flexor phase (see two bottom trace in Fig. 7B2). Consequently, each stimulus prolonged the duration of the ongoing locomotor cycle and hence produced a phase shift of the poststimulation locomotor rhythm (see arrows at the bottom of Fig. 7B2).

Based on the results of these simulations, it can be concluded that stimulation of extensor afferents during extension may prolong the current extension phase with or without changing the duration of ongoing locomotor cycle and the phase of poststimulation rhythm. The exact effect in the two-level locomotor CPG model depends on how strongly the applied stimulation influences the RG level of the CPG.

Effects of Flexor Afferent Stimulation

The flexor side of the reflex circuitry operating during fictive locomotion has an organization with several similarities to that affecting the extensor side of the CPG. Flexor afferent stimulation can also evoke disynaptic excitation in flexor motoneurons that are modulated with cycle phase (Degtyarenko et al. 1998; Quevedo et al. 2000). However, compared to the disynaptic excitation of extensors by extensor afferents, the disynaptic excitation of flexors has a more complex phase dependency and a more limited distribution to hind limb flexor motoneurons (Quevedo et al. 2000). Therefore, a disynaptic excitation of flexors has not been included in the reduced model containing only two motoneuron pools.

There is experimental evidence that activation of group II afferents in flexor nerves during fictive locomotion can either terminate the ongoing flexor phase and switch the step cycle to extension (e.g., following TA nerve stimulation) or prolong ongoing flexor activity (e.g., EDL nerve stimulation) (Perreault et al. 1995; Stecina et al. 2005). Occasionally, these actions reverse spontaneously (Stecina et al. 2005). In the same preparations, flexor group I afferent activation can enhance and prolong flexor motoneuron activity in a manner analogous to the extensor-promoting actions of extensor group I afferents (Perreault et al. 1995; Stecina et al. 2005). These observations support the suggestion that the group I flexor afferents are excitatory to the flexor part of the CPG (i.e., to the RG-F and PF-F populations in the model). The hypothesis was suggested that while flexor group I afferents excite the flexor part of the CPG (both the RG-F and PF-F populations), flexor group II afferents are excitatory to the extensor part of the CPG (see Stecina et al. 2005). Accordingly, the effects of simultaneous activation of group II and group I flexor afferents work against each other. The resulting effect is, therefore, dependent upon

T

Two-Level Model of Mammalian Locomotor CPG, Fig. 7 (continued) at the *bottom*). In contrast, in the simulation shown in B2, similar to the experimental example shown in A2, the flexor phases following the stimulus-

evoked prolonged extensor phases did not shorten, and the corresponding step-cycle periods increased. (Adapted from Rybak et al. (2006b) with permission)

the interplay between the two influences on the CPG.

The schematic of the model used for flexor afferent stimulation is shown in Fig. 8. Similar to the organization postulated for extensor afferents, the hypothetical Irg-F and Ipf-F populations were incorporated to mediate the effect of flexor group I afferents on the RG and PF levels, respectively (Fig. 8). The excitatory effect of flexor group I afferents on PF-F interneurons (via the Ipf-F population) was relatively strong compared to their effect on the RG-F population (via Irg-F). To reflect the hypothesis that flexor group II afferents have an excitatory influence to the extensor part of the CPG, connections from flexor group II muscle spindle afferents to the Irg-E and Ipf-E populations were incorporated in the model. Because of the strong weighting of group II afferent input to the RG-E population (via Irg-E), activation of these afferents may strongly affect

Two-Level Model of Mammalian Locomotor CPG, Fig. 8 Schematic of the model used for simulation of flexor afferent stimulation. Flexor group I afferents (*Ia* and *Ib*) (green lines) access the RG-F and PF-F populations of the CPG through interneuron populations (*Irg-F* and *Ipf-F*, respectively, both are shown green). Flexor group II afferents (blue lines) project to the extensor side of the CPG via the *Irg-E* and *Ipf-E* populations, respectively (shown blue). (Reproduced from Rybak et al. (2006b) with permission)

the rhythm generator (e.g., produce a resetting the RG to extension).

Figure 9A shows an example of the effects of flexor afferent stimulation during flexion. Stimulation of TA afferents at an intensity recruiting group II fibers (5 T, where T is the threshold for activation of group I afferents in the peripheral nerve) terminated ongoing flexor phase activity (hip/knee flexor, Sart) and reset extensor activity (hip, SmAB, and ankle, MG), while stimulation of EDL nerve prolonged flexion (hip/knee, Sart, PerL). The first stimulus in this experiment reduced the ongoing cycle period shifting the rhythm to the left, while the second stimulus of a higher intensity caused a prolongation of the duration of both the ongoing flexion and the total cycle period (and the corresponding shifting of the rhythm to the right). Figure 9B shows an example of simulation of the effects of flexor afferent stimulation during flexion. To match the experimental procedure, all stimuli were applied to both flexor group I (*Ia* and *Ib*) and group II afferents. The first stimulus (left, see black rectangles at the top of traces in Fig. 9B) strongly recruits both group I and II afferents. This stimulus terminated the ongoing flexion phase and reset the cycle to extension (see the RG-F and RG-E activities, first and second traces, in Fig. 9B). In order to mimic a less effective recruitment of group II afferents, the threshold for activation of group II flexor afferents was increased prior to the application of the second stimulus. Such stimulation prolonged the ongoing flexor phase because the relatively stronger group I activation evoked excitation of the PF-F population and prevented phase resetting at the PF level (see third and fourth traces in Fig. 9B) and hence at the level of motoneurons (see two bottom traces in Fig. 9B). Therefore, the net result of strong activation of flexor group I and relatively weak activation of group II afferents was a prolongation of the ongoing flexion phase. It is important to notice that both stimuli reset the RG rhythm in the model (see first and second traces in Fig. 9B). Note that increasing the threshold of group II afferents in the model reduced their input to the *Irg-E* and *Ipf-E* populations and produced an effect similar to the experimental data shown in Fig. 9A. It can be suggested that the

Two-Level Model of Mammalian Locomotor CPG, Fig. 9 Modeling the effects of stimulation of flexor afferents during flexion. **(A)** Example of stimulation of TA afferents (5 T) during flexor phase in fictive locomotion experiments. Stimulation of TA afferents terminated the flexion phase (hip/knee, *Sart* and *PerL*) and advanced the onset of extensor (hip, *SmAB*, and ankle, *GS*) activity. Stimulation of another flexor nerve (*EDL*) in the same run of fictive locomotion prolonged the ongoing flexion phase (see activities of *Sart* and *PerL*). **(B)** Results of simulation reproducing the effects of stimulation of the group II flexor afferents during flexion shown in **A**. Tonic drives to the RG-F and RG-E populations were adjusted to fit the experimental data. The applied stimuli are shown as black rectangles at the top of traces. The first stimulus

terminated ongoing flexion and initiated a premature onset of extension. Before application of the second stimulus (see vertical dotted line between two stimuli), the threshold of group II flexor afferent activation was increased from $\text{Thr(II)} = 2.5$ to $\text{Thr(II)} = 4.27$ (see labels at the top). As a result, the second stimulus produced the prolongation of the ongoing flexion phase (PF-F and Mn-F activities, *third* and *fifth* traces). Note that both stimulus presentations reset the RG activity (RG-F and RG-E, see *top two traces*). In both the simulation and experiment, the locomotor rhythm was affected by stimulation of the flexor nerve with the first stimulation shortening and the second prolonging the ongoing locomotor period (see *arrows below traces*). (Adapted from Rybak et al. (2006a) with permission)

reflex actions of group II afferents between different flexor nerves could vary according to either the numbers of group I and II afferents in each nerve or their central excitatory effectiveness.

Figure 10A1–A5 shows experimentally recorded effects of EDL nerve stimulation taken

from different fictive locomotion experiments (McCrea 2001; Stecina et al. 2005). During these experiments, the same intensity of stimulation (activating both group I and II afferents) resulted in a variety of effects on the step cycle. This variety of effects may result from the differences

Two-Level Model of Mammalian Locomotor CPG,

Fig. 10 Modeling the variable effects on locomotor output evoked by flexor muscle afferent stimulation during flexion. (**A1–A5**) Experimentally recorded effects of 5 T stimulation of EDL afferents during the flexion phase of MLR-evoked fictive locomotion. Averaged ENG records during cycles in which stimulation was applied (*perturbed cycle*) are shown by *thick lines*. The records during control (*unperturbed*) cycles are shown below the corresponding perturbed cycles. These observations were selected from different experiments and formed the basis of the simulations shown in **B1–B5**. Note the variety of effects observed following 5 T EDL stimulation. In **A1**, EDL stimulation resulted in a slight increase in flexor (*Sart*) activity and with no effect on the timing of flexor or extensor motoneuron bursts. In **A2**, there was a prolongation of the ongoing flexion phase and a delay in the activation of extensors. In **A3** and **A4**, flexor afferent stimulation also prolonged the flexion phase (see *Sart* in **A3** and *Psoas* in **A4**), but there

was also a brief reduction in flexor motoneuron activity in the middle of the flexor phase and a corresponding small but visible activation of extensors (see hint of extensor activity in *LGS* in **A3**). Both these effects presumably indicate a fast resetting of flexor activity. Another stimulus trial from the same run of fictive locomotion as shown in panel **A4**, shows a rare example of a spontaneous reversal of EDL actions (see **A5**). In this example, stimulation of EDL afferents initiated a premature onset of extension, terminating the flexion phase. (**B1–B5**) Simulation results illustrating variable effects of stimulation of flexor afferents (*black rectangles*) during the flexion phase. The threshold of group II flexor afferent activation, Thr(II) , was sequentially decreased from *left to right* (see values of Thr(II) at the *top* of each panel). *Black rectangles* at the *top* of traces indicate timing and duration of the applied stimuli. Note that the applied stimuli reset the rhythm generator in all simulations except for **B1** (see *first* and *second* traces showing the RG-F and RG-E population

in the excitability of the CPG networks or from the differences in the effectiveness of synaptic transmission from group I and II afferents to the CPG network (Perreault et al. 1999). In the first example (Fig. 10A1), EDL stimulation produced only a slight increase in hip flexor (Sart) activity, and there was no effect on step-cycle period (compare the cycle period in the perturbed cycle to that in the unperturbed cycle). In the second experiment (Fig. 10A2), EDL stimulation prolonged the ongoing flexor motoneuron bursts (hip, Sart) and delayed the onset of extensor bursts (ankle, GS). In Fig. 10A3, A4, flexor afferent stimulation also prolonged the flexion phase (hip, Sart and Psoas), but there was also a brief reduction in flexor motoneuron activity in the middle of the flexor phase and a corresponding small but visible activation of extensors (in Fig. 10A3). Both of these effects presumably indicate a fast resetting of flexor activity. Figure 10A5 shows an example of the unusual effect of EDL nerve stimulation terminating flexion and initiating a premature onset of extension (Stecina et al. 2005). This example was from the same run of fictive locomotion as shown in Fig. 10A4 and represents an example of a spontaneous reversal of EDL actions. This “reversed” extension-promoting action of EDL stimulation is similar to the common effect seen with TA nerve stimulation (Perreault et al. 1995; Stecina et al. 2005).

Figure 10B1–B5 shows the effects of a progressive increase in the influence of flexor group II afferents on the RG-E and PF-E populations in the model. This progressive increase was produced by reducing the threshold for group II flexor afferent activation (see threshold value at the top of each panel). At the lowest level of group II activation (highest threshold, Fig. 10B1), the

stimulation had little effect on the RG populations and produced a mild enhancement and prolongation of flexor motoneuron activity due to the activation of the PF-F population by flexor group I afferents (see third and fourth traces in Fig. 10B1). These effects can be compared to the experimental data shown in Fig. 10A1. In Fig. 10B2–B5, the threshold for group II flexor afferent activation was sequentially reduced until it was the same as the first stimulus in Fig. 9B. In Fig. 10B2, B3, the group II activation resets the RG (see first and second traces), but this resetting was not expressed at the PF level (see third and fourth traces). As a result the flexor motoneuron activity was prolonged similar to the experimental data shown in Fig. 10A2, A3, even though activity in the flexor half-center of the CPG (RG-F) was shortened. In Fig. 10B4, the increased group II input (further threshold reduction) produced further excitation of the extensor side of the CPG (RG-E, see second trace). This partially overcame the group I actions on the flexor side, and a phase resetting occurred at both the RG and PF levels, as happened in experiment shown in Fig. 10A4. There was, however, only a small brief burst of extensor motoneuron activity and a short break in flexor activity. Further reduction of the threshold for group II flexor afferent produced much stronger group II effects on the CPG (see Fig. 10B5): the flexion phase was terminated, and there was a clear resetting to a new extensor phase, which reproduces the experimental results shown in Fig. 10A5. As seen in Fig. 10B5, this resetting to extension could be reproduced in the model by further recruitment of flexor group II fibers. In all but one (Fig. 10B1) of the simulations shown in Fig. 10B1–B5, the prolongation of flexion or resetting to extension was accompanied by a resetting of the rhythm at the RG level of the CPG.

T

Two-Level Model of Mammalian Locomotor CPG, Fig. 10 (continued) activities). In **B2** and **B3**, the concomitant activation of PF-F by flexor group I afferents (see Fig. 8) prevented resetting at the PF level (*third and fourth traces in B2 and B3*) and the level of motoneurons (*bottom two traces*). The result, therefore, was a prolongation of the flexion phase. In **B4**, the applied stimulus produced only a

short break in the middle of flexor activity and a small, short extensor burst (Mn-E, *bottom trace*). In **B5**, with the lowest Thr(II), sensory activation was strong enough to produce an irreversible resetting to extension (see text for details). (Adapted from Rybak et al. (2006a) with permission)

Conclusion

In summary, the modeling studies have demonstrated that the two-level CPG organization with separate RG and PF networks can provide a plausible explanation for a number of features of real CPG network operation, such as spontaneous resetting and non-resetting deletions and the effect of afferent stimulations observed during fictive locomotion. The proposed two-level model of the locomotor CPG may create a flexible basis for development of a more elaborated and realistic model of neural control of locomotion.

Definition

The unitary event (UE) analysis is a statistical method that detects conspicuous patterns of

synchronous spiking activity among simultaneously recorded spike trains. Significant patterns are identified by comparison of their occurrence counts to the null hypothesis of statistical independence based on the activity of the neurons.

Detailed Description

It has been proposed that cortical neurons organize dynamically into functional groups (“cell assemblies”) by the temporal structure of their joint spiking activity. The unitary event analysis method is designed to detect such patterns of coincident spiking activity occurring more often than expected by chance among simultaneously recorded single neurons. To this end, the spiking activity of all simultaneously recorded neurons is represented, after appropriate time discretization (e.g., $h = 1$ ms), as parallel sequences of zeros and ones, “1” indicating the existence of at least one spike (clipping) and “0” the absence of spikes (Fig. 1a). From this representation, the number of occurrences for each of the individual 0–1 patterns across the neurons is counted. There are at most 2^N different coincidence patterns in data of N simultaneously observed neurons. Due to the finite recording time and the dominance of zeros, however, the actual number of different coincidence patterns found is typically much lower. A unique index k is assigned to each existing pattern based on some arbitrary sorting. Next, for each pattern k , the number of occurrences

Unitary Event Analysis, Fig. 1 Binary data representation of N parallel spike trains within a data stretch of T bins of width h . **(b)** Distribution of coincidences given the expected number n_{exp} . Significance (p-value, black area)

of the number of empirically found coincidences n_{emp} . **(c)** Transformation of the p-value into the surprise measure S . The arrow indicates the surprise value corresponding to the identified p-value (jp) in **b**. (Modified from Grün (2009))

termed the empirical count is determined. To derive the *significance* of a pattern k , the p-value of its number of occurrences is calculated by comparison to the probability distribution derived under the null hypothesis of statistical independence of the processes. The distribution either can, under certain conditions, be assumed and adjusted by parameters estimated from the data (parametric approach) or can be derived with Monte Carlo methods by the generation of surrogate data on the basis of the original data (nonparametric approach).

The parametric approach has the following assumptions: (a) the firing rates are stationary within the time span of the observation T , and (b) the processes have Poisson properties. Then the expected number of occurrences of a pattern k can *analytically* be calculated based on the firing rates of the neurons. For each neuron i , the probability of firing within a bin p_i is derived by dividing the number of bins occupied by a spike c_i by the total number of bins in T , i.e., T/h , with h the bin width. The joint probability for pattern k , P_{exp}^k , to occur by chance is then calculated as the product of the firing probabilities p_i for the neurons contributing a spike in pattern k and probabilities $1 - p_i$ for neurons contributing a 0 to the pattern. The expected number of occurrences of pattern k is derived as $n_{\text{exp}}^k = P_{\text{exp}}^k \cdot T/h$. This quantity defines the mean of the Poisson distribution that is used to estimate the significance of the pattern by calculation of its p-value, i.e., the area under the distribution from n_{emp}^k to infinity. If the p-value is smaller or equal to a predefined

significance level α , the pattern is considered to occur significantly more often than by chance. If the p-value is larger or equal to $1 - \alpha$, the pattern is occurring significantly less often than expected. The p-value may be expressed as the surprise measure (Fig. 1c), a logarithmic transformation of the p-value (Grün et al. 2002a) for better visualization (Fig. 2c).

Often experimental data exhibit violations of the above assumptions, i.e., firing rates may change even on a short timescales or spike trains deviate from Poisson statistics. In the latter case, the coincidence distribution is not well described anymore by a Poisson distribution (e.g., Pipa et al. 2013), since the process type influences the distribution. If firing rate changes are not properly considered, the estimated mean of the distribution may not be correct. If such cases are ignored, this may lead to false-positive outcomes and wrong interpretation of the data (Grün 2009; Grün et al. 2010). Thus, an alternative approach for the estimation of the significance is based on a numerical (Monte Carlo) method, in which the original data are manipulated to destroy potential spike synchrony but conserve all other features of the spike trains. One example is spike dithering, i.e., the random displacement of each individual spike within a small time window (e.g., Pipa et al. 2003; for details and alternative approaches, see Louis et al. 2010a, b). The resulting surrogate data are then analyzed like the original data for the number of occurrences of patterns of interest. Pattern counts from many repetitions of this procedure realizing the null hypothesis of independence form the distribution, which

modulation of synchronous activity. UE analysis of two simultaneously recorded single neurons from motor cortex of awake behaving monkey. The monkey was involved in a delayed pointing task, where the duration of the preparation period (after PS) to the requested movement (RS) was selected randomly from four possible durations (600, 900, 1200, 1500 ms) from trial to trial. Here trials (36) with the longest duration (1500 ms) were pooled. (a) Raster displays of spike discharges of two neurons. (b) Comparison of measured (black) and expected (gray) coincidence rates. Allowed coincidence width ± 2 ms. (c) Surprise as a function of trial time. (d) Dot display with unitary events (squares) detected based on a significance level of $\alpha = 0.05$, in sliding windows of $T = 100$ ms. (Modified from Riehle et al. (1997))

is then used for the significance estimation of the empirical pattern count.

When aiming at the analysis of the correlation structure of the neuronal spiking activity in relation to behavior, which is dynamic by nature, the analysis has to be performed in a time-dependent manner. Also the firing rates typically change in time which needs to be accounted for. Therefore, the UE analysis is applied within a time window of length T (i.e., 100 ms duration) that is slid along the data (for proper choice of the analysis window, see Grün et al. 2002b). This enables the study of the dynamics of the correlation structure. It was found in a number of studies that spike synchronization modulates in time in relation to the behavioral context (e.g., Riehle et al. 1997; Grün et al. 1999; Riehle et al. 2000; Maldonado et al. 2008; Kilavik et al. 2009; Ito et al. 2011).

The experiments are typically repeated over several trials to improve the statistics of the analysis. For this purpose, the trial data are aligned to an (behavioral) event of interest. The analysis window is then slit along the aligned data, and at each window position, the data of the same time segment are jointly considered. The empirical pattern counts are derived by summing the occurrence counts of the same pattern in the different trials to provide the empirical count ($\hat{n}_{\text{emp}}^k = \sum_j n_{\text{emp}}^{kj}$). In the parametric approach, the expected number is calculated trial by trial and then summed to the total number ($\hat{n}_{\text{exp}}^k = \sum_j n_{\text{exp}}^{kj}$) providing the mean of the distribution as introduced above. Taking the sum instead of an estimate based on average firing rates across trials has the advantage to account

for cross-trial non-stationarities in the firing rates (Grün et al. 2003). For the nonparametric approach, the count across trials is compared to the count distribution derived from surrogates by the sum of counts of the surrogates across the trials. For population measures, i.e., for statistics of the data across several sessions, one may proceed by adding more trial data, however now resulting from the different sessions (see for details Kilavik et al. 2009).

In 2017 the unitary event analysis was newly implemented in Python and is available in the open source Electrophysiology Analysis Toolbox (Elephant, RRID:SCR_003833) at <http://python-elephant.org>. One of the unit tests of the Python UE implementation is the reimplement of the UE analysis performed in Riehle et al. (1997) published as Rostami et al. (2017) in ReScience. Therein Rostami et al. showed that the UEs are identically and correctly detected on a spike-by-spike basis. The data and code is fully available from <https://github.com/ReScience-Archives/Rostami-Ito-Denker-Gruen-2017/tree/master/article>.

This method is not designed to detect higher-order correlations, since the null hypothesis is statistical independence. Shimazaki et al. (2012) extended the approach within the information geometry framework. This identifies in a time-dependent manner higher-order spike correlation patterns. The analyses of massively parallel spike data (e.g., in the range of 100 neurons) require statistical methods that either ignore the individual spike patterns (e.g., Staude et al. 2010a, b) or pool across patterns to avoid severe multiple testing problems (Picado-Muiño et al. 2013; Torre et al. 2013, 2016a, b; Stella et al. 2019).

Vestibular Adaptation and Compensation

Thomas P. Wellings, Alan M. Brichta and Rebecca Lim
School of Biomedical Sciences and Pharmacy,

University of Newcastle, Callaghan, NSW,
Australia

Definition

There are two forms of adult neuroplasticity associated with the vestibular system: *vestibular adaptation* and *vestibular compensation*. Vestibular adaptation describes the routine changes in sensitivity (gain) of reflexive eye movements (vestibulo-ocular reflex, VOR) responsible for stabilizing images on the retina during head movements. Vestibular compensation, however, is a form of plasticity only precipitated by catastrophic events such as loss of vestibular input on one side.

Detailed Description

The balance or vestibular system is often overlooked as a major sensory system (Goldberg et al. [2012](#)).

Even less appreciated is the vestibular system's inherent plasticity and capacity for self-repair. Two phenomena known as *vestibular adaptation* and *vestibular compensation* are exquisite examples of innate plasticity. The extent and limits of these restorative mechanisms can be observed and measured by using the important vestibulo-ocular reflex (VOR) as an example.

Vestibulo-Ocular Reflex (VOR)

In all animals, including humans, the VOR is a vestibular-mediated reflex that helps maintain a stable image on the retina, a critical prerequisite for visual acuity. In response to head movement in

one direction, the VOR generates compensatory eye movements that are usually equal in magnitude but opposite in direction. The VOR is very rapid and has one of the shortest activation latency (9–15 ms) of any reflex that involves motor output (Aw et al. 1996; Minor et al. 1999). This speed is due in large part to its deceptively simple circuitry, often described as a three-neuron arc that consists of the following: (1) vestibular primary afferent neurons that transmit balance signals from the inner ear to vestibular nuclei, (2) vestibular nucleus (VN) neurons that receive additional multisensory information and send “balance” signals to various motor nuclei that control eye movements, and (3) motor neurons that innervate extraocular eye muscles (Fig. 1).

Vestibular Adaptation and Compensation, Fig. 1 A circuit diagram emphasizing the three-neuron arc involved in the horizontal vestibulo-ocular reflex (VOR). The VOR is responsible for generating compensatory eye movements during changes in head orientation. In this example, rotation of the head to the left (green arrows) results in eye movements to the right (orange arrows). Turning the head to the right causes inner ear fluid, in the right horizontal semicircular canal, to flow in the excitatory direction (blue arrow), thereby increasing signals from associated hair cells and primary afferents. Simultaneously, in the

right horizontal semicircular canal, fluid flows in the inhibitory direction (red arrow) resulting in *decreased* signals from associated hair cells and primary afferents. Peripheral signals from both sides are transmitted to their respective vestibular nuclear complexes and preferentially target the medial vestibular nuclei (MVN). From the MVN, signals are conveyed along either excitatory (blue) or inhibitory (red) pathways via cranial motor nuclei (abducens and oculomotor) to extraocular muscles, resulting in compensatory eye movements

Vestibular Adaptation

While the concept of a three-neuron arc may help explain the speed of the VOR, it does not adequately describe the VOR's remarkable ability to adapt. When viewing a far object, the eyes move as described above – equal but opposite to head movements. Under these conditions, therefore, we can quantify VOR sensitivity or *gain* as being equal to unity (dividing eye velocity by head velocity). However, there are common situations where VOR gain must be modified to maintain visual stability (Angelaki 2004; Migliaccio and Schubert 2013). For example, if an object is viewed nearer to the subject, eye movements increase and have to be corrected not only for their larger excursions but also for *vergence*, where both eyes deviate inwards towards the nose. It is therefore a basic requirement that the VOR and eye movements reflexively adapt to the viewing context, including viewing distance and vergence angle (Migliaccio et al. 2003). In short, to minimize retinal image slip, when the vestibular-evoked eye movements are not perfectly compensatory, the VOR must undergo a process of *vestibular adaptation* (Melvill Jones and Gonshor 1982; Baker et al. 1987; Clendaniel et al. 2002). An extreme example of the VOR's remarkable adaptive capacity is known as *cross-axis adaptation*. Here a visual scene is moved at right angles to head motion. Within 30–120 min of training, the VOR can reduce vertical eye movements in response to horizontal head rotations in the dark, with no visual or proprioceptive cues (Schultheis and Robinson 1981; Khater et al. 1990). Although cross-axis adaptation would rarely occur in nature, it is a manifestation of vestibular adaptation, an astonishing and poorly understood or appreciated example of adult neuronal plasticity. How vestibular adaptation is achieved at the cellular level is not known, but a detailed analysis of the neuronal circuitry involved and the changes it undergoes are a necessary first step.

Vestibular Compensation

Another striking example of adult neuronal plasticity associated with the vestibular system is a phenomenon known as *vestibular compensation*

(Smith and Curthoys 1989; Curthoys 2000). Immediately after disruption or loss of peripheral nerve activity on one side, due to disease or damage (e.g., neuritis, labyrinthitis, or unilateral labyrinthectomy), there is a stereotyped series of behavioral deficits including imbalance, spontaneous nystagmus (slow eye drift towards the injured side with fast corrections in the opposite direction), head tilt, postural deficits, and reduced VOR (Curthoys and Halmagyi 1999; Lasker et al. 2000). Over the following several days to 1 week, there is a near resolution of *static symptoms* (i.e., symptoms in the absence of head movement). This process of recovery is the result of changes in central rather than peripheral vestibular system, since compensation occurs independent of peripheral nerve activity. There are, however, limits to vestibular compensation, despite the recovery from static symptoms (Curthoys and Halmagyi 1995). Deficits observed during head movements, *dynamic symptoms*, such as reduced VOR, are never fully restored.

Vestibular Nucleus (VN) Activity

The cellular basis of the stereotyped compensatory responses and subsequent vestibular compensation is also not fully understood. From classical in vivo recordings (Precht and Shimazu 1965; Shimazu and Precht 1965), we know, at rest, VN neurons on both sides maintain similar spontaneous background discharge rates. In response to a rotation of the head to the left, there is an increase in primary afferent and VN neuronal activity on the *left* side with a concomitant decrease in primary afferent and VN neuronal discharge on the right side. Both left and right VN signals contribute to VOR-induced compensatory eye movements and in this case move the eyes to the *right*.

Cellular Mechanisms Underlying Plasticity and Self-Repair

Acute loss of peripheral input on the left side induces decreased VN activity on the left and increased VN activity on the right (Curthoys and Halmagyi 1995; Ris and Godaux 1998). This

condition simulates an apparent head movement to the *right*. In response, the VOR produces compensatory nystagmus with slow eye movements to the *left*, towards the affected side. During the subsequent period of vestibular compensation, however, the asymmetry between VN neuronal activity on the left and right sides begins to abate as background discharge of left VN neurons is reestablished. This realignment of activity is on a similar time scale to the resolution of static vestibular deficits, including nystagmus. Further studies suggest, however, this rebalance of background activity in VN neurons may be one of many factors responsible for the resolution of static symptoms (Curthoys 2000). As with *adaptation*, the cellular mechanisms underlying *compensation* in the central vestibular system still remain a major goal for vestibular neuroscience.

Vestibular Function After Cochlear Implantation

Stephen O’Leary

University of Melbourne, Melbourne, VIC, Australia

Synonyms

[Balance following cochlear implantation](#); [Equilibrium following cochlear implantation](#)

Definition

Cochlear implantation is a surgical procedure where an electrode array is implanted into the cochlea (hearing part of the inner ear). The electrode electrically stimulates the cochlear nerve resulting in auditory percepts that assist with speech reception. Vestibular function estimates the response of the semicircular canals to angular velocity and the utricle and saccule to linear acceleration. The sense of equilibrium results from the integration of visual, proprioceptive and vestibular sensory information within the brainstem and central nervous system. In other words, vestibular function is a vital, but not the sole, factor contributing to the sense of balance.

Detailed Description

Vestibular function is vulnerable during cochlear implantation because the latter breaches the integrity of the labyrinth, putting both residual hearing and vestibular function at risk.

The response of the lateral semicircular to bithermal stimulation (the “caloric” response) is reduced following cochlear implantation. The unilateral weakness score (as calculated from Jongkees’ formula) is typically increased by an average of 20–30% towards the implanted ear (Ito 1998; Enticott et al. 2006, 2011). While it has been suggested that the surgery to the temporal bone done in preparation to implantation may change the caloric response, by altering thermal conduction through the temporal bone, this has been shown to make a relatively small contribution to the caloric response, compared with that made by cochlear implantation (Kondoh et al. 2009). Approximately 10% of patients lose the majority of their caloric function in the implanted ear, suggesting significant injury to the vestibular system in that ear.

The vestibular ocular reflex (VOR) gain estimated from quantitative head impulse testing (by video assessment, or scleral search coils) does not change after cochlear implantation in the majority of patients (Jutila et al. 2013; Melvin et al. 2009). However, the VOR gain is lost in approximately 10% of patients.

More than half of patients experience a reduction in their cervical vestibular evoked myogenic potentials following cochlear implantation, and the potentials are lost in approximately 10% of patients (Melvin et al. 2009; Licameli et al. 2009). These potentials are thought to arise from the saccule.

In summary, in studies conducted in the 1990s and early 2000s a significant reduction in vestibular function within the implanted ear was found in approximately 10% of patients. The incidence of dizziness after CI surgery is much greater, ranging from between 30% and 50% patients (Enticott et al. 2006; Fina et al. 2003; Ito 1998). The majority of patients experience a transient dizziness in the first few weeks after surgery that resolves completely (Enticott et al. 2011; Ito 1998), but the onset of the dizziness can be delayed for months after implantation. Delayed dizziness can be either head-position dependent and respond to treatment for benign paroxysmal positional vertigo, or fluctuate and resemble that experienced in Meniere’s disease (endolymphatic hydrops) (Ito 1998). Risk factors for delayed post-operative dizziness include poorer pre-operative vestibular dysfunction and older age at the time of implantation and duration of hearing loss (Fina et al. 2003). The incidence of post-operative dizziness can be reduced by the local application of glucocorticosteroids to the round window during cochlear implant surgery, prior to electrode insertion (Enticott et al. 2011).

Injury to the cochlear duct following cochlear implantation might explain the loss of vestibular function seen in some patients after cochlear implantation (Handzel et al. 2006). Histology from human cochlear implant patients has revealed that electrode insertion can lead to injury of the cochlear duct, and subsequent fibrosis and obliteration of the endolymphatic space. The cochlear duct is vulnerable because it is located just above the basilar membrane, and in close proximity to the electrode path within scala tympani. The cochlear duct may be injured through incorrect placement of the cochleostomy, or by the electrode passing inadvertently through the basilar membrane. Scarring within the endolymphatic space has been associated with collapse of the saccule in human temporal bones (Handzel et al.

2006; Tien and Linthicum 2002), likely due to a reduction in the endolymphatic flow from the cochlea to the vestibular labyrinth. This provides one potential explanation for the significant loss of vestibular function seen in some patients after cochlear implantation.

The reason(s) why so many patients become dizzy for a short period of time after cochlear implantation are not well understood. Potential mechanisms include the development of serous labyrinthitis in response to inner ear surgery, and injury to the lateral cochlear wall during electrode insertion, resulting in a loss of regulation of ionic homeostasis within the inner ear. The latter might lead to endolymphatic hydrops and consequently dizziness in patients with a patent cochlear duct (Handzel et al. 2006). The presence of hydrops in human temporal bones (Handzel et al. 2006) may also explain the delayed Meniere's-like vertigo seen in some cochlear implant patients.

A rare cause of dizziness following cochlear implantation is direct electrical stimulation of the vestibular nerve (Coordes et al. 2012). This has presented as dizziness when some or all of a cochlear implant's electrodes have been electrically stimulated. Cervical vestibular evoked myogenic potentials have on occasion been elicited through electrical stimulation of the implant electrodes (Coordes et al. 2012). It has been postulated that low-level electrical stimulation of the vestibular nerve may in fact *improve* the balance of cochlear implant recipients; several studies have shown that the sense of balance is improved when the cochlear implant is functioning (Cushing et al. 2008). It remains unclear as to whether this is due to a direct effect upon the vestibular system, or improved situational awareness through being able to hear.

Clinically, the majority of patients do not experience any lasting disturbance of their sense of balance following cochlear implantation, even when there was been a significant reduction in the vestibular function within the implanted ear. This can be attributed to central compensation following peripheral vestibular injury, and that the sense of equilibrium results from an integration of vestibular, visual and proprioceptive

inputs. The risk of on-going disequilibrium increases slightly following bilateral cochlear implantation, presumably because of the associated risk of bilateral injury to the vestibular system. For this reason, vestibular function testing is recommended prior to cochlear implantation, and in particular second-side surgery in vulnerable individuals, such as older persons where a loss of balance may compromise independence of living or those involved in jobs that require exquisite balance.

Vestibular Otoliths, Response to Vibration and Sound

Ian S. Curthoys

School of Psychology, University of Sydney,
Sydney, NSW, Australia

Definition

Vestibular receptors are hair cells, which are very similar in structure and operation to cochlear hair cells. Recently it has been shown that afferent nerves from otolithic receptor hair cells in the striola of the otolithic sense organs – the utricular and saccular maculae – respond to vibration and sound. That has quickly been translated to clinical application by measuring myogenic potentials elicited by sound and vibration. The saccular macula and the utricular macula have differential projections to various muscle groups, and that has been used to index the differential function of saccular and utricular maculae. The cervical vestibular evoked myogenic potential (cVEMP) indicates mainly the saccular function and the ocular vestibular evoked myogenic potential (oVEMP) indicates mainly the utricular function.

Detailed Description

Introduction

The otolithic receptors of the vestibular system of the inner ear (the utricular and saccular maculae) sense linear acceleration and generate a host of compensatory responses and perceptions. However, assessment of the functional state of the otolithic receptors has been a major challenge. The standard approach has been to deliver linear accelerations and measure the responses to that stimulus. Various methods of delivering linear accelerations have been used – e.g., tilt chairs, sleds, and centrifuges. These systems are excellent devices for research but not for everyday clinical practice where it is necessary to obtain accurate data safely, simply, and quickly.

One solution to this problem was the discovery of small myogenic potentials recorded by

electromyographic (EMG) electrodes on the surface of the skin over the activated muscles (Colebatch and Halmagyi 1992). These EMG potentials triggered by sound and vibration are now called vestibular evoked myogenic potentials (VEMPs). This approach is built on two important premises:

1. Control experiments that show that VEMPs are vestibular and are not of cochlear origin – deaf patients with vestibular function have VEMPs, whereas patients without vestibular function but with good hearing do not have VEMPs (Colebatch and Halmagyi 1992; Colebatch et al. 1994).
2. Neurophysiological evidence that vestibular receptors are activated by sound and vibration which is discussed below

The two most commonly measured VEMPs are the ocular VEMP (oVEMP) measuring the myogenic potentials of the inferior oblique (IO) eye muscle (Rosengren et al. 2005; Weber et al. 2012) and the cervical VEMP (cVEMP) measuring the potentials in the tensed sternocleidomastoid (SCM) neck muscle (Colebatch and Halmagyi 1992). These two VEMPs are evoked by sound and vibration, but they have very different characteristics. The first negative component of the oVEMP (n10) is a small ($\sim 5\text{--}10\ \mu\text{V}$) negative myogenic potential at a latency of about 10 ms recorded from beneath the eyes as the subject looks up. It is a crossed negative (excitatory) potential from the IO originating primarily from utricular afferents coursing in the superior division of the vestibular nerve. In contrast the first positive component of the cVEMP (p13–n23), recorded over the SCM tensed by the subject lifting or turning their head, is an uncrossed positive (inhibitory) potential originating primarily from saccular afferents coursing in the inferior vestibular nerve (Curthoys 2010, 2012; Rosengren and Kingma 2013; Shin et al. 2012; Manzari et al. 2012).

The Stimulus

In these studies the stimulus is an air-conducted sound (ACS) or a bone-conducted vibration

(BCV), and a brief tap or burst of 500 Hz BCV has been shown to be very effective. BCV applied to the head causes waves to travel through and around the skull and cause linear accelerations at the mastoids (Iwasaki et al. 2008b). A vibration or light tap to the midline of the forehead at the hairline (a location called Fz) with a tendon hammer causes linear accelerations at the mastoids, with both mastoids moving outward, obviously not by much, but the linear acceleration is present and otoliths sense linear accelerations. That has been shown by using miniature lightweight surface-mount triaxial linear accelerometers on the mastoid to measure the linear accelerations at the mastoid in response to a tap of the forehead. Fz is a valuable location because a tap at that location causes simultaneous equal linear acceleration stimulation of both mastoids. The magnitude of the linear acceleration is greatly attenuated from the forehead to the mastoid, so a light tap by a tendon hammer measures 20 g at the forehead, but at the mastoid this is a 0.2 g linear acceleration – an attenuation by a factor of 100.

The evidence that the VEMPs are vestibular comes from tests on patients with a surgically verified loss of unilateral vestibular function which show a greatly reduced or absent oVEMP beneath the eye contralateral to the affected ear (the oVEMP is crossed) and a greatly reduced or absent cVEMP response of the neck muscles on the same side as the affected ear (the cVEMP is uncrossed).

Projections

Afferent neurons from the vestibular receptors project to the brainstem vestibular nuclei and thence to the neurons controlling many different motor functions to generate oculomotor and postural responses.

Neural Evidence

What is needed is a strong evidence that sound and vibration activate vestibular receptors and afferents. The major questions here are whether both the otolith and semicircular canal neurons are equally affected and whether both the utricular and saccular afferents are activated by both ACS and BCV.

Extracellular single neuron recording of primary vestibular afferents shows that it is almost exclusively otolith afferents with irregular resting discharge which respond to 500 Hz ACS and BCV (Curthoys et al. 2006) (Fig. 1). Semicircular canal neurons and regular otolith neurons are only rarely activated by this frequency and then only at very high intensities. The sites of origin of these neurons have been shown by using electroporation (juxtacellular injection) of neurobiotin on these otolith irregular neurons and then removing the whole utricular and saccular maculae and using immunohistochemistry to stain and then trace the labeled neurons (Curthoys et al. 2012). Since the maculae were removed, it was possible to see from which macula the labeled neurons originated and precisely where on the macula they originate from. The axons of activated neurons originate from the receptors in or close to the striolar area of both the utricular and the saccular maculae (Curthoys et al. 2012). There is now no doubt that both utricular and saccular afferents show sensitive response to *both* ACS and BCV stimuli – conclusively falsifying what was the widely held view that ACS only activates the saccular afferents (Curthoys and Vulovic 2011).

The origin of these otolith irregular afferents from the region of the striola is in agreement with evidence from Goldberg (2000) – calyx afferents innervating type I receptors are localized preferentially to the striola of the utricular and saccular maculae, and these otolith irregular afferents are especially sensitive to changes in linear acceleration (jerk) and that jerk sensitivity may be the reason why these afferents are so sensitive to bone-conducted vibration. 500 Hz BCV consists of 500 rapid changes in linear acceleration per second. It is the type I receptors at the striola which are especially vulnerable to the effects of ototoxic antibiotics.

Recent evidence is that low-frequency vibration (100 Hz) does activate semicircular canal afferents, but 500 Hz is selective just for otolith neurons.

In 2010 Curthoys put forward the hypothesis that by measuring the different *responses* to otolith stimuli, it is possible to assess the utricular as opposed to the saccular function because these

Vestibular Otoliths, Response to Vibration and Sound, Fig. 1 (a) Time series of an irregular otolith neuron during stimulation by 500 Hz BCV and ACS. The top trace (a) shows the command voltage indicating when the stimulus is presented. The second trace shows the extracellular recording. The three bottom traces (x, y, z) show the triaxial accelerometer recording of the stimulus. The left panel is an example of BCV stimulation, and the right panel is an example of ACS stimulation of the same neuron. Note the scale of stimulus intensity in g units at the left margin between traces x and y. (b) Examples of

sensitivity plots of the neurons to BCV. Each point shows the increase in firing rate as the percentage of baseline firing rate during a single stimulus presentation. The stimulus intensity is calculated in g units and is the root mean square of three axes, as recorded by the accelerometers, for BCV, and for ACS, intensity is given in dB SPL. Each line shows the linear best fit of the responses for one neuron. The red X marks show the mean ABR thresholds with 95% confidence intervals for clicks, one- and two-cycle tone stimuli (Reproduced with permission from Curthoys and Vulovic (2011))

different otolithic sensory regions have predominantly different projections (Curthoys 2010), specifically that:

- Utricular function is probed by recording VEMPs from electrodes beneath the eyes (the oVEMP n10) to 500 Hz ACS or BCV as the patient looks upward because the utricular afferents have a strong projection to the eye muscles.
- Saccular function is probed by recording VEMPs from electrodes on tensed SCM muscles in the neck (the cVEMP p13–n23) to 500 Hz ACS or BCV, because the saccular afferents have a strong projection to the neck muscles.

Vestibular Otoliths, Response to Vibration and Sound, Fig. 2 (a, b) A simplified schematic version of some of the known neural vestibuloocular and vestibulo-colic projections that appear to underlie the asymmetric oVEMP and cVEMP responses after unilateral vestibular loss. It is based on known anatomical projections and physiological results that high-frequency electrical stimulation of the utricular nerve results in the activation of the contralateral inferior oblique (IO) and the ipsilateral superior oblique. Electrodes over the inferior oblique (circles) record the oVEMP. Afferents from the saccular and

utricle maculae project to the vestibular nuclei, but the exact termination of these afferents is not presently known, so this figure represents the present uncertainty about the exact neural connections of these afferents within the vestibular nuclei as an open box. The otolithic projections to other eye muscles are not shown. The projections of the saccular macula in the inferior vestibular nerve, synapsing on an inhibitory neuron in the vestibular nucleus (black hexagon), projecting to spinal motoneurons controlling the SCM, are established by Uchino et al. (2005). Electrodes over contracted SCM muscles record the cVEMP.

The crucial point is that the neural studies show that the same stimuli (ACS and BCV) activate both the utricular and saccular afferents, so it is not possible to deduce the utricular or saccular function according to the stimulus (ACS or BCV) presented; *receptors in both maculae respond to both stimuli*. By assessing the responses due to the differential neural projections, it is possible to come up with specific tests of the utricular and saccular function. The published evidence supports this hypothesis.

Practical Application

To apply these neural data to the measurement of patient responses in the clinic, we use a vibrator – a Bruel and Kjaer 4810 minishaker – to deliver 7 ms bursts typically of 500 Hz BCV at Fz. Usually 50 presentations of these stimuli at a rate of 3/s at moderate intensities (about the strength of a body massager) are used which is not stressful or uncomfortable. High-intensity 120 dB SPL 500 Hz air-conducted sound also evokes oVEMPs and cVEMPs. For the oVEMP the subject must be looking up in order to maximize the oVEMP n10. The small excitatory potential, the n10 component of the oVEMP, occurs at a latency of around 10 ms, and in response to stimulation at Fz, the n10 beneath both eyes in healthy subjects is about equal. In contrast, in patients after complete unilateral vestibular nerve loss, the oVEMP n10 is greatly reduced or absent beneath the eye opposite to the affected ear – the oVEMP is a crossed utriculo-ocular response. In these patients there is a large asymmetry of the oVEMP n10 response (Iwasaki et al. 2008a; Manzari et al. 2010a).

These same unilateral patients show a reduced or absent cVEMP p13 on the side of the affected ear – the cVEMP is an uncrossed sacculo-colic response. Since the oVEMP n10 is predominantly of utricular origin, then patients with loss of *just* the superior division of the vestibular nerve show reduced or absent oVEMP n10 beneath the contralateral eye because all the utricular afferents course in the superior vestibular nerve and eventually project to the contralateral IO. In these patients the cVEMPs are unaffected (Manzari et al. 2010b; Iwasaki et al. 2009). Conversely patients with loss of *just* the inferior division of the vestibular nerve show reduced or absent cVEMP p13–n23 on the ipsilesional side, because the saccular afferents course in the inferior division of the vestibular nerve and project to ipsilateral SCM, but the oVEMP n10 is unaffected (Manzari et al. 2012; Fig. 2).

Clinical Significance of These Results

This basic scientific work has very clear benefits for clinical testing of human otolithic function, since it allows most clinics to assess the functional status of the otoliths very simply by using an averager and audiometer (which most audiological clinics have) just by changing the location of the recording electrodes. The clinician can use air-conducted sound via the audiometer headphones to measure mainly the utricular and saccular function (Curthoys 2012).

Summary

Anatomically identified otolithic afferents are activated by BCV (and many also by ACS) at low

Vestibular Otoliths, Response to Vibration and Sound, Fig. 2 (continued) Unilateral vestibular loss results in reduced or absent contralateral oVEMP n10 and a reduced or absent ipsilateral cVEMP p13–n23. (c) Examples of averaged EMG responses: oVEMP and cVEMP responses for a healthy subject (*column 1*), a patient with right unilateral vestibular loss (*column 2*), and a patient with left superior vestibular neuritis (*column 3*). The yellow and blue vertical bands mark the time of healthy oVEMP n10 and cVEMP p13 responses, respectively. The healthy subject displays n10 responses of similar magnitude and likewise p13–n23 responses of similar amplitude. The patient with right unilateral vestibular loss has normal n10 responses beneath the right (ipsilesional) eye and in

the left (contralesional) SCM and absent responses beneath the left (contralesional) eye and in the right (ipsilesional) SCM. Because oVEMPs are a crossed response (Iwasaki et al. 2007) and cVEMPs are an uncrossed response, these results are consistent with complete loss of otolithic function on the right side. The patient with left superior vestibular neuritis, on the other hand, shows absent oVEMPs beneath the right (contralesional) eye, a normal oVEMP response beneath the left (ipsilesional) eye, and normal cVEMPs on both sides. This is consistent with oVEMPs being a predominantly utricular response and cVEMPs being a predominantly saccular response (Reproduced with permission from Curthoys et al. (2011))

threshold and high sensitivity. Anatomical evidence shows that these sensitive afferents originate from both the utricular and saccular maculae.

In conclusion, otolith irregular afferents are activated at low threshold and high sensitivity by 500 Hz BCV and ACS. These afferents come from both the utricular and saccular maculae. The same BCV elicits vestibular, not auditory, eye movements in animals and humans. It has been shown conclusively that single afferents from the utricular macula do respond to both ACS and BCV, and that result justifies the use of ACS to test oVEMPs in the clinic as an indicator of mainly the utricular function (Curthoys 2012). This result also firmly establishes that what is important in clinical testing of otolith function is not the method of stimulation (ACS vs BCV) but rather the response that is measured.

Hopkins University, Baltimore, MD, USA

Definition

A vestibular prosthesis is an implantable neural stimulator system designed to restore sensation of head movement for individuals who have lost the mechanotransduction function of hair cells in both inner ear labyrinths. Similar to cochlear implants (which sense sound using a microphone, decompose that sound into independent components, and then electrically stimulate the cochlear nerve), a vestibular prosthesis senses head motion using inertial sensors and conveys head angular velocity information to the corresponding branches of the vestibular nerve.

Detailed Description

Normal Vestibular Function

In normal individuals, sensation of head rotation, orientation, and translation originates in the semi-circular canals (SCCs) and otoconial end organs in each labyrinth. The two labyrinths modulate activity on afferent fibers within each of the five vestibular nerve branches so as to provide the

central nervous system with information regarding the head's 3-dimensional (3D) rotational velocity, translational acceleration, and tilt with respect to gravity. Vestibular sensory input drives compensatory reflexes that stabilize gaze and posture, maximizing clarity of vision during head movement, minimizing the risk of falling, and helping to maintain normal perception of body position and trajectory (Carey and Della Santina 2005).

Input of Prosthesis: Interface Between Head Movement and Prosthesis Input

Inputs to a vestibular prosthesis are provided by micromachined sensors, which can be either single-axis (Gong and Merfeld 2000, 2002) or three-axis gyroscopes and linear accelerometers (Della Santina et al. 2007; Chiang et al. 2011). Gyroscope signals are filtered digitally and/or via analog circuitry to attenuate noise and frequency components outside the range of normal SCC performance. Additional filtering may be performed in an attempt to better fit the dynamics and latency of electrically evoked responses to natural VOR responses. Linear accelerometer signals can be used to report the orientation of a stationary device with respect to the skull (which must be measured to later map sensor signals to output channels of the prosthesis) (Chiang et al. 2011).

Prosthesis Processing: Interface Between Input Signal and Output Signals Through Microcontroller/Processor

The filtered signals from each of the three mutually orthogonal gyroscope sensors are sampled by a microcontroller and assembled into a vector representing 3D head angular velocity in a multi-channel vestibular prosthesis (Della Santina et al. 2007; Chiang et al. 2011). The microcontroller then maps head rotation signals to changes in the pulse frequency and amplitude of current pulse trains delivered to the vestibular nerve's branches via an array of electrodes in the implanted labyrinth (Gong and Merfeld 2000, 2002; Della Santina et al. 2007; Chiang et al. 2011).

To prevent electrode corrosion and evolution of gas or other toxic substances at each electrode's

metal-saline interface due to faradaic (oxidation-reduction) reactions (Robblee and Rose 1990; Merrill et al. 2005), vestibular prosthetic stimulation pulses are typically biphasic and charge-balanced between phases (Bonham and Litvak 2008). Some implementations also allow pulses to be asymmetric, typically using a “cathodic pseudomonophasic” approach in which a relatively brief and high-amplitude cathodic phase is charge-balanced by a relatively long and low-current anodic phase (Hayden et al. 2011; Macherey et al. 2011).

A multichannel vestibular prosthesis may contain multiple, independent current sources that allow the microcontroller to distribute stimulus current across multiple electrodes simultaneously in tripolar and quadropolar arrangements intended to steer current toward target axons and away from nontarget tissue (Fridman and Della Santina 2012). Improved spatial resolution in cochlear

implants has been achieved using similar current steering approaches (Bonham and Litvak 2008).

Prosthesis Output: Interface Between Electrode Stimulation and Afferent Vestibular Nerve

The efficacy of vestibular prosthesis stimulation largely depends on accuracy of targeting each SCC nerve branch, which requires precise surgical placement of electrodes in the vestibular labyrinth to maximize electrode-nerve coupling with a target ampullary nerve branch while minimizing misalignment of the head motion percept (and resulting reflexive eye and postural movements) due to spurious stimulation of nontarget branches.

Selectivity of stimulation depends on the stimulation paradigm employed. Monopolar stimulation via a single active electrode in each ampulla (with current returned via a distant electrode

Vestibular Prosthesis, Interface, Fig. 1 Common signal processing elements used in vestibular prosthesis design (Fridman and Della Santina 2012). Gyroscopes sense head rotation about each axis corresponding to the SCC orientations. These angular velocity signals are filtered to more closely emulate the transfer function of the SCC hydrodynamics. Linear coordinate transformation uses matrix M to pre-correct for misalignment between the axis and velocity of the actual head rotation and those of the head movement sensation evoked by electrode

stimulation. The corrected velocity signals are then mapped to amplitude and pulse rate specifications for each electrode implanted in the left anterior and right posterior (*LARP*), right posterior and left anterior (*RALP*), and horizontal (*H*) SCCs. These pulse rate and pulse-amplitude specifications are combined with constant stimulus parameters (stimulation and reference electrode selection and pulse width of current pulses) by the pulse-generation algorithm and circuitry to deliver biphasic charge-balanced stimuli to the electrodes

outside the labyrinth) achieves strong coupling with the target nerve branch but also significant current spread to nontarget branches. Bipolar electrode pairs positioned transverse to the axis of the ampulla and perpendicular to the distal trajectory of the target nerve elicit more focal stimulation and greater selectivity, but they must be positioned precisely to achieve these benefits (Hayden et al. 2011). Electrode array designs that incorporate a trio of electrodes within each of three silicone leads are designed to self-orient and locate electrodes near target tissue when surgically inserted into the ampullae (Chiang et al. 2011). By positioning multiple electrode contacts near the sensory neuroepithelium of each SCC, these electrode designs increase the probability that at least one electrode will be adjacent to the target tissue, allow the use of bipolar and tripolar stimulation paradigms (Chiang et al. 2011), and facilitate estimation of how stimulation coupling and misalignment depend on electrode location (Fig. 1).

Vestibular System: Introduction

G. M. Halmagyi¹ and Ian S. Curthoys²

²School of Psychology, University of Sydney, Sydney, NSW, Australia

Definition

The peripheral vestibular system comprises ten three-dimensional inertial motion sensors, five in each inner ear. They are mirrored pairs; the four otoliths (utricle and saccule) sense the linear acceleration and position of the head in space, and the six semicircular canals (Fig. 1) sense angular acceleration of the head. It is an ancient system even present in some invertebrates (Carey and Della Santina 2010; Baloh and Kerber 2011; Goldberg et al. 2012).

Vestibular System: Introduction,

Fig. 1 Labyrinth. Showing the orientation of the semicircular canals in the human

Detailed Description

When hair cell processes on the maculae of the otoliths in each inner ear are deflected by the inertia of the otoconia, or those on the cristae of the canals by inertia of the endolymphatic fluid in the canal duct, action potentials are generated in the vestibular nerves, proportional to head position and motion (Figs. 2 and 3).

The vestibular nerves connect with neurons in the vestibular nuclei which then connect to other brainstem nuclei, the cerebellum, the cortex, and the spinal cord (Fig. 4).

What benefit is vestibular information? The best answer to this question is the human who has lost all vestibular function but is otherwise intact. In such cases it is only the loss of vestibular information to the brainstem and the spinal cord that seems to cause problems: jiggling vision while moving (oscillopsia) due to loss of vestibulo-ocular reflexes (Fig. 5), and postural imbalance especially on uneven surfaces and in the dark due to loss of vestibulospinal reflexes.

Since any angular motion of the head is immediately counteracted by an (almost) irresistible, exactly equal, and opposite reflex motion of the eyes, measuring these vestibulo-ocular reflexes is an accurate and robust way to measure canal function. The eyes are in a sense the speedometers of the ears – they will rotate at exactly the same speed about exactly the same axis as does the head. Without (angular) vestibulo-ocular reflexes motion

of the head is no longer opposed by motion of the eyes so that the line of sight is no longer fixed. Retinal images now move with head motion and the result is oscillopsia. The otoliths, especially the utricle, also produce vestibulo-ocular reflexes and these can be measured by recording short latency electromyography (EMG) activity in extraocular muscles in response to sound or vibration (Rosengren and Kingma 2013; see also Fig. 6).

Testable human vestibulospinal reflexes mainly originate from the saccule and loss of these causes imbalance especially when vision and proprioception are both impaired. These can also be tested by measuring short latency EMG activation in response to sound and vibration, especially in certain neck muscles.

Vestibular information to the cerebellum is widespread and complex, but from a functional basis only its interaction with the angular vestibulo-ocular reflex is testable. There can be an additive interaction when a subject views an earth fixed target (the visual vestibulo-ocular reflex) or a subtractive interaction when the subject views an head-fixed target (visual suppression of the vestibulo-ocular reflex) (Fig. 7).

Vestibular information to the cerebral cortex can be tested but reliably only in rigorous, arduous psychophysical experiments in normal subjects. It is, however, important to the patient with a common clinical problem: acute unilateral loss of vestibular function (“doctor, I feel so dizzy”). And so is vestibular information to brainstem

Vestibular System: Introduction, Fig. 2 (a) Vestibular sensory epithelium and its innervation. *HCI* type I hair cell, *HCII* type II hair cell, *St* stereocilia, *KC* kinocilia [*kc*, modified kinocilia and roots (*b*) of supporting cells, (*S*)]; *N* nerve fiber, *NC* nerve calyx, *NE* nerve endings, *Sy* synaptic structures, *G* Golgi membranes, *RM* multi-vesicular reticular membrane, *E* endoplasmic reticulum,

Philadelphia: University of Pennsylvania Press, 1966:39, with permission). (b) Electronmicrograph of vestibular hair cell (Courtesy of Dr Anna Lysakowski)

Vestibular System: Introduction, Fig. 3 The bidirectional responses of a single vestibular hair cell. There is a level of resting activity. Displacement of the hair cell processes (stereocilia) in one direction (that is towards the largest hair cell process – the kinocilium) increases the firing rate of the vestibular neuron synapsing with the

hair cell, whereas displacement in the opposite direction reduces the firing rate. Whereas it is nearly impossible to saturate the firing rate in the excitatory direction it is easy to do in the inhibitory direction. This inherent asymmetry is the physiological basis of the Head Impulse Test (see below)

Vestibular System: Introduction,

Fig. 4 Schematic representation of the vestibular pathways from primary afferent neurons in Scarpa's ganglion to the ipsilateral vestibular nuclei and from there to the cerebellum, spinal cord, reticular formation (RF) and cerebral cortex. The contralateral projections are not shown. Note there is a direct project of primary afferents to the cerebellum (Figure by David Kachlik; with permission from http://anatomie.lf3.cuni.cz/anglickaverze/cns_drahavestibulami_eng.htm)

autonomic nuclei, especially area postrema (“doctor, I feel so sick”).

What then happens if the vestibular system on one side (one labyrinth) is destroyed by disease or design? The functional deficit produced by a unilateral lesion of the vestibular system is determined by whether the lesion developed suddenly or slowly and, if suddenly, how long ago. Acute destruction or deafferentation of one entire intact labyrinth, in animal or human, by disease or by design, invariably produces an acute, temporary, stereotyped clinical syndrome of profound motor and sensory abnormalities. There is, due to otolithic deafferentation, a complete or, more often, partial ocular tilt reaction that is always ipsiversive (toward the side of the lesion) (Fig. 8). The complete ocular tilt reaction consists of ipsilesional head tilt, ipsilesional conjugate binocular eye torsion, and an ipsilesional hypotropia due to skew deviation (vertical dysconjugacy of the visual axes causing double vision). Owing to semicircular canal deafferentation, there is also a spontaneous horizontal-torsional nystagmus (a continuous

rhythmic saw-tooth wave-form jerking of the eyes, with the slow phases toward the side of the lesion), as well as vomiting. Humans, and perhaps animals, experience vertigo and nausea. These symptoms and signs make up the syndrome of acute unilateral vestibular deafferentation (uVD). Although normally both humans and animals recover, more or less completely, from the acute uVD syndrome by the process of vestibular compensation, the vestibulo-ocular reflex is permanently damaged. From studies of the acute uVD syndrome and of the processes of vestibular compensation in experimental animals, one could infer that peripheral vestibular disorders produce vertigo when there is asymmetric neural activity between corresponding parts of the left and right vestibular nuclei, and that recovery from the acute uVD syndrome is due to rebalancing of the neural activity in the vestibular nuclei on the two sides. One could also infer that a person not experiencing vertigo should, at that time, have symmetrical vestibular nucleus activity.

Once vestibular compensation is complete, so that there is a chronic stable uVD, the patient will

Vestibular System: Introduction, Fig. 5 Measurement of horizontal eye movement in response to sinusoidal horizontal head rotation in a patient with total bilateral vestibular loss from gentamicin toxicity staring at an earth-fixed target. During head shaking up to about 1.5 Hz and 50 deg/s angular head velocity, gaze velocity (i. e., eye-in-space) velocity is close to zero, as it would be in a normal subject, so that the patient would perceive no target movement. (There are some tiny saccadic eye

movements – spikes on the velocity recording; these are irrelevant). As the frequency of head shaking increases, gaze velocity increases so that at 5 Hz and 100 deg/s peak angular head velocity, gaze velocity is about 50 deg/s. The basic explanation is simple: at low frequencies and angular head velocities the visual reflexes (pursuit and optokinetic) will generate accurate compensatory eye movements; at high frequencies and velocities only the vestibulo-ocular reflex is able to do so

no longer experience vertigo, and most patients will experience no symptoms at all. In other words, most patients cannot tell if they have unilateral vestibular loss. A minority of patients, about 20 %, with a chronic stable uVD will experience postural imbalance and oscillopsia, symptoms experienced by all patients with bilateral vestibular deafferentation and described in more detail below.

In contrast, chronic progressive uVD, as would occur with a slowly growing tumor such as a vestibular schwannoma, does not produce the acute uVD syndrome of vertigo, nausea, vomiting, nystagmus, and ocular tilt reaction.

This is presumably because there is never a prolonged period of asymmetrical neural activity in the vestibular nuclei. In fact, if a patient presents with signs of uVD and categorically denies ever having experienced an attack of acute spontaneous vertigo, one can be almost sure that the uVD has not been acute, and one should therefore look for a potential progressive cause of uVD.

What happens if now the other labyrinth is destroyed? After compensation for uVD has occurred, acute deafferentation of the other labyrinth produces a second acute uVD syndrome. If, however, the second uVD is carried out soon after the first, before compensation has occurred, a

Vestibular System: Introduction, Fig. 6 Absent ocular vestibular evoked myogenic potentials (*oVEMPs*) during the acute phase of left superior vestibular neuritis. The n10 potential of the *oVEMP* (c) is missing from the right eye recording (originates in the left utricle) whereas the left

cervical VEMP (d; originates in the the left saccule) is present. Video Head Impulse Test (a, b) shows the expected impairment of left lateral semicircular canal function (see also Fig. 11) (From Manzari et al. 2011, with permission)

Vestibular System: Introduction, Fig. 7 Absent visually enhanced horizontal vestibulo-ocular reflex in a patient with combined loss of semicircular canal function and of cerebellar function impairing both the vestibulo-

ocular reflex and smooth pursuit. Horizontal head velocity is in *red*, inverted horizontal eye velocity is in *black*. Note the salvos of catch-up saccades (grey trace)

Vestibular System: Introduction, Fig. 8 Head-eye posture in a normal, gravitationally vertical subject (*center*), in a normal subject tilted to the right (*left*), and in a patient with a leftward ocular tilt reaction (*right*). The *left panel* shows the normal compensatory leftward ocular tilt reaction in response to rightward roll-tilt stimulation. The *right panel* shows a pathologic tonic leftward ocular tilt reaction which could be due to a lesion of the left

labyrinth, left vestibular nerve, left vestibular nucleus, or right meso-diencephalon. The normal subject's response to rightward roll-tilt stimulation is leftward head tilt, leftward eye torsion (i.e., counter-rolling), and a left skew deviation (left hypotropia). Note that alone and even together the head tilt and eye torsion are normally incompletely compensatory (From Halmagyi et al. 1990)

second uVD syndrome will not develop. Indeed, if the second uVD is carried out while the symptoms of the first are at their peak, the uVD symptoms will terminate – the so-called Bechterew effect – If the two labyrinths are deafferented simultaneously, either suddenly or slowly, the patient will not experience vertigo, since there is no left-right asymmetry in vestibular nucleus activity. The long-term effects of bilateral vestibular deafferentation are the same irrespective of whether uVD occurred simultaneously or sequentially (Curthoys and Halmagyi 2014). The patient will be off balance and have oscillopsia (but will never again be motion sick).

What then happens if one labyrinth is stimulated? Each semicircular canal (SCC) has its signature nystagmus, so that it is possible to deduce from an analysis of the nystagmus rotation axis the exact SCC which gives rise to it, for example, in patients with benign positional vertigo, paroxysmal nystagmus due to stimulation of ampullary

hair cells by otoconia in one SCC (Fig. 9). If the nystagmus is predominantly horizontal, then the otoconia are in the lateral SCC. If the nystagmus is upbeat and torsional, then the otoconia are in the posterior SCC. The rotation axis of the nystagmus is orthogonal to the plane of the affected SCC in these patients. In patients with sound- and pressure-induced vestibular symptoms due to superior (anterior) semicircular canal dehiscence, the induced nystagmus has downbeat and torsional quick phases, so that the rotation axis of the nystagmus is orthogonal to the plane of the superior (anterior) SCC.

The standard caloric test is also based on labyrinthine stimulation. Warm (44 °C) or cool (30 °C) water infused into the patient's external auditory canal creates a thermal gradient across the labyrinth and generates a convective movement of lateral canal endolymph, which then deflects the cupula and either increases or decreases the firing rate of SCC primary afferent

Vestibular System: Introduction, Fig. 9 The nystagmus of benign positional vertigo (BPV). Horizontal, vertical and torsional position and velocity of the left eye during the provocative Hallpike test in a patient with canalithiasis of the right posterior semicircular canal producing benign paroxysmal positioning vertigo and as shown here nystagmus. As the patient is pitched backwards with the right ear

down there is a normal vestibulo-ocular reflex. Almost as soon as the patient reaches this position there is a paroxysm of nystagmus lasting about 10 s with quick phases beating clockwise (from the patient's point of view) upward and to the left – slow phases in the opposite direction (For more details see Aw et al. (2005))

Vestibular System: Introduction, Fig. 10 Electrically evoked VORs to human bipolar electrical vestibular stimulation (EVS) in healthy subjects, bilateral and unilateral vestibular deafferented patients. (A) Normal eVOR from healthy subjects (N = 17) (group means $\pm$ 6 SEM) comprised conjugate torsional and horizontal eye rotations, binocularly equal in amplitude, rotated away from cathode towards anode, and vertical divergence with the intorting eye upwards (cathode side) and extorting eye downwards (anode side). (B) EVOR was absent from patients with bilateral vestibular deafferentation (BVD) (N = 5) with torsional, vertical and horizontal eVOR positions. (C)

Bidirectional eVOR from grouped as right UVD patients with left functioning ear (N = 12). The excitatory eVOR to left-cathode/right-anode (lc/ra) cathodal EVS comprised conjugate torsional and horizontal eye rotations away from cathode and a vertical divergence with the eye on the anodal side moving downwards. The inhibitory eVOR to right-cathode/left-anode (rc/la) anodal EVS was in the opposite direction and at about half the amplitude of the excitatory eVOR with the eye on the anodal side moving upwards. (The schemes illustrate EVS polarities and eye rotation directions) (From Aw et al. 2013)

Vestibular System: Introduction, Fig. 11 (continued)

neurons. The caloric test is mainly a test of lateral SCC function, because the lateral SCC is the closest to the thermal stimulus and, with the patient supine and the head elevated 30° from horizontal, it is earth vertical resulting in a large convective effect.

It is also possible to stimulate the otolithic organs on one side. In the cat, electrical stimulation of the utricular nerve results in a contraversive ocular tilt reaction comprising conjugate contraversive eye torsion, contraversive head tilt, and skew deviation with contralateral hypotropia. In humans, galvanic mastoid stimulation produces a similar response (Fig. 10). Loud clicks will activate the saccule and the utricle and produce an inhibitory potential, the vestibular-evoked myogenic potential (VEMP), in the tonically contracting ipsilateral sternomastoid neck muscles and contralateral inferior oblique extraocular muscles as well as in jaw muscles.

What then is the best way to test semicircular canal function in humans? These days the answer would have to be impulsive testing in which an examiner holds and turns the subject's head rapidly in one direction. The rotation need not be large. It should be a 20–30 deg peak amplitude, 150–300 deg/s peak velocity, and 2000–5000 deg/s/s peak acceleration, unpredictable, head rotation approximately in the plane of a SCC pair. The physiological principles behind impulsive testing are understood. Due to the bidirectional, morphological, and physiological polarization of the hair cell bundles on the cristae, the SCCs operate as push-pull pairs. During any head rotation, displacement of the stereocilia toward the kinocilium depolarizes the hair cell and generates excitation, while displacement of stereocilia away from the kinocilium hyperpolarizes the hair cell and generates inhibition. In response to a head rotation such

as a head impulse, one SCC of the push-pull pair is excited while the other is inhibited, generating the total angular vestibulo-ocular reflex (VOR) from direct excitation and indirect disinhibition. In the lateral (horizontal) SCC, ampullopetal endolymph flow causes excitation while ampullofugal flow causes inhibition whereas in the vertical SCCs ampullofugal flow causes excitation and ampullopetal flow causes inhibition. It is this directional polarization which produces the on-off directional asymmetry of the VOR generated by a single SCC summarized in what is called Ewald's 2nd Law and is a means of identifying impairment of individual SCC function.

The smooth eye movement response to a head impulse is too fast to allow any contribution to the compensatory eye movement from smooth pursuit or cervico-ocular reflexes: it is generated exclusively by the VOR. During the head impulse in normal subjects with close to unity VOR gain (eye velocity/head velocity magnitudes), both eyes rotate instantly and smoothly in the compensatory direction and thus keep fixing on target whereas a patient with reduced VOR gain cannot keep looking at the fixation target and has to make a usually observable catch-up saccade in order to refixate the target. Scaled head impulses can be produced manually with a visual head velocity feedback signal for the examiner. Individual lateral SCCs can be tested with head impulses about the yaw axis to excite the ipsilateral and inhibit the contralateral lateral canal. Individual vertical SCCs can be tested along their approximate right-anterior and left-posterior (RALP) and left-anterior and right-posterior (LARP) planes (Fig. 11).

The search coil technique has been the gold-standard method to measure head and eye position in impulsive VOR testing. Head and eye positions

Vestibular System: Introduction,
Fig. 11 Simultaneous video and scleral search coil Head Impulse Test in a patient with loss of function of all three semicircular canals on the left following intratympanic gentamicin treatment (figure on *left*) and in a patient with right superior semicircular canal dehiscence and selective loss of right anterior (i.e., superior) canal function (figure on *right*). Normally smooth eye velocity (here

inverted and shown in *green*) matches head velocity (*blue*). If there is a deficit in the vestibulo-ocular reflex from any semicircular canal then smooth vestibulo-ocular reflex eye velocity will be less than head velocity and will be compensated by catch-up saccades (shown in *red*). The readily available video method gives essentially the same result as the traditional research based search coil method. For more details see MacDougall et al. (2013)

can be recorded in two dimensions with single-search coils or in three dimensions with dual-search coils. Recent work shows that simple-to-use video methods, which for clinical diagnostic purposes produce results equivalent to the search-coil method, have been rapidly incorporated into clinical practice (MacDougall et al. 2013; Curthoys et al. 2014).

Vestibular, Canal Testing: The Head Impulse Test

Swee T. Aw

Central Clinical School, University of Sydney, Sydney, NSW, Australia

Institute of Clinical Neuroscience, Royal Prince Alfred Hospital, Sydney, NSW, Australia

Definition

The head impulse test (HIT) measures individual horizontal (lateral), superior, and posterior semicircular canal function in the high-frequency range (Aw et al. 2001; Halmagyi and Curthoys 1988). The HIT is an unpredictable, passive, low-amplitude (10–20°), high-acceleration (2000–4000°/s²) head rotation approximately along the semicircular canal planes executed manually either by an operator or by an electro-mechanical device. It is performed with subjects seated upright fixating on a straight-ahead target.

How the Head Impulse Test Works

The angular vestibulo-ocular reflex (VOR)'s function is to stabilize vision during head rotations and is mediated by the horizontal, superior, and posterior canals in the labyrinth which transduce rotational head accelerations. During the HIT, one semicircular canal of the push-pull pair in the plane of the head rotation is excited, while the other is inhibited, generating the total angular VOR from direct excitation and indirect disinhibition. Mechano-electrical transduction converts the deflection of the unidirectionally polarized hair cell stereocilia (the canal sensors) during head rotation into electrical receptor potentials to generate neural impulses and vestibular responses.

Yaw (horizontal) plane impulses (rotations about the Z-axis) excite the ipsilateral and inhibit the contralateral horizontal canal (Fig. 1). The vertical canal pairs can also be individually

Vestibular, Canal Testing: The Head Impulse Test, Fig. 1 Head-fixed coordinate system obeying the right-hand rule used to express angular eye position and velocity vectors. Yaw plane impulses are head rotations about the Z-axis used to test the horizontal (lateral) canals. Head impulses, respectively, in LARP (*left-anterior right-posterior*) and RALP (*right-anterior left-posterior*) canal planes test the vertical canal pairs. Other impulses include pitch plane impulses, i.e., head rotations about the Y-axis and roll plane impulses, i.e., head rotations about the X-axis

excited along their approximate right-anterior and left-posterior (RALP) and left-anterior and right-posterior (LARP) planes to activate the respective superior and posterior canal pairs. Pitch plane impulses (rotations about the Y-axis) excite both superior and inhibit both posterior canals during pitch-down and vice versa during pitch-up. Roll plane impulses (rotations about the X-axis) excite the ipsilateral superior and posterior canals and inhibit the contralateral superior and posterior canals. Clinically, the HIT provides fast, reliable, bedside screening of semicircular canal dysfunction by observation of the overt refixation saccade to HIT towards the paretic canal with an angular VOR deficit.

Recording the Head Impulse Test

Search Coil System: The search coil technique is the preferred method of measuring the HIT. Head and eye positions can be recorded in 2D

(horizontal and vertical) with single-search coils or in 3D (horizontal, vertical, and torsional) with dual-search coils using two- or three-field magnetic field systems (CNC Engineering, or Rempel, USA). The subject is seated with the head in the center of the magnetic fields wearing pre-calibrated monocular or binocular search coils on the eyes to measure angular eye positions, while another search coil is attached to a dental impression bite bar (recommended to prevent head coil slippage) to measure angular head positions (Aw et al. 2001; Carey et al. 2002; Cremer et al. 1998).

Video-Oculography System

Video-oculography has been used recently to measure yaw head impulses. It comprises goggles mounted with one to two video cameras worn by the subject (GN Otometrics and EyeSeeCam). Angular (orientation in yaw, pitch, and roll coordinates) and linear (position in X, Y, and Z coordinates) head movements in six degrees-of-freedom are recorded by an inertial measurement unit. Limitations in its use include video-camera detector slip which can be mistaken as a normal VOR response. Measurement of vertical canal function with video is only an approximation when using 2D (pupil-tracking) techniques.

Data Analysis

Head, gaze, and eye positions are analyzed in 3D as rotation vectors, quaternions, or Euler angles. Head and gaze positions are the head and eye orientations in space-fixed coordinates, and eye position is the eye orientation in head-fixed coordinates. Head, gaze, and eye velocities are calculated from their respective positions in 3D. To analyze the angular VOR related to the superior and posterior canal pairs, the coordinate reference frame is rotated by 45° about the yaw (Z)-axis to allow re-expression of these vectors as rotations about the approximate preferred axis of individual vertical canals (Fig. 1). The angular VOR in response to a head impulse is analyzed in the first 80–100 ms period after impulse onset because saccades and blinks are usually absent in this period.

Individual Semicircular Canal Function

Angular VOR Gain

Individual semicircular canal function measured with the HIT is quantified as angular VOR gain at close to peak head velocity using: (a) velocity gain, i.e., eye velocity divided by head velocity; (b) acceleration gain determined as the ratio between the slopes of eye and head velocities for a fixed period; and (c) impulsive canal paresis, which measures the gaze instability in 3D when the head is rotated towards a paretic canal, defined as the ratio of gaze velocity to head velocity in semicircular canal coordinates.

VOR Direction

The direction of the input-output kinematics of the angular VOR can be quantified as a misalignment angle in 3D, the instantaneous angle by which the eye rotation axis deviates from perfect alignment with the head rotation axis.

VOR Latency

The VOR latency to head impulses has been estimated to be ~6–10 ms and is defined as the minimum time interval between least square fits to the head and eye velocity traces, respectively, while head velocity is in the range between 20°/s and 70°/s.

Refixation Saccade

When the head is rotated rapidly about the plane of a semicircular canal, the angular VOR generates compensatory eye movements approximately equal in amplitude but in the opposite direction in order to stabilize gaze in space. During rapid rotation towards the side of a peripheral vestibular lesion, any angular VOR deficit results in loss of normal compensatory eye movements, and the patient makes a “catch-up” or refixation saccade in order to relocate the target as instructed. Observation of these refixation saccades forms the basis of a clinical judgment of individual semicircular canal function at the bedside. These refixation saccades have been classified as covert or overt saccades. Covert saccades occur during head rotation and are imperceptible to a clinical observer. Overt saccades appear after head rotation and are detectable by the clinician (Fig. 2b).

Head Impulse Response in Normals and After Total Unilateral Loss

Figure 2 shows typical examples of the angular VOR in response to yaw head impulses from a normal subject and a subject with total unilateral loss after unilateral vestibular deafferentation

Vestibular, Canal Testing: The Head Impulse Test, Fig. 2 Typical examples of eye rotation responses to yaw head impulses from (a) a healthy normal subject and (b) a patient after left unilateral vestibular deafferentation (UVD). Eye signals are inverted for comparison with head signals. In the normal subject, the compensatory horizontal

eye velocity to a yaw-left impulse is equal and opposite to head velocity and results in stable gaze. The loss of left horizontal canal function after UVD results in lower compensatory horizontal eye velocity than head velocity, and thus, an eye position error occurs. Both covert and overt refixation saccades (arrows) were used to stabilize the gaze

(UVD). In the normal subject, eye velocity is approximately equal and opposite to head velocity, and normal VOR gain in response to yaw impulses is ~ 0.9 – 1.0 in humans (Figs. 2a and 3a). After UVD, the angular VOR in response to yaw head impulses directed towards the left deafferented semicircular canal is deficient, and the VOR gain was low at ~ 0.1 – 0.3 and eye position errors occur (Fig. 2b). The HIT response can be spatially compared between normal and UVD by plotting eye velocity as a function of head velocity. In the left UVD subject, there was a significant deficit during yaw-left (ipsilesional) head impulses (Fig. 2c) (Weber et al. 2008).

Loss of Semicircular Canal Function in Vestibular Neuritis

Vestibular neuritis is an acute unilateral peripheral vestibulopathy presenting with a clinical syndrome of vertigo, nystagmus, postural imbalance, nausea, and vomiting without brain stem dysfunction. HIT of individual semicircular canal function enabled the assessment of the extent of

involvement of the vestibular nerve or the labyrinth by vestibular neuritis (Fig. 3). The superior vestibular nerve innervates the lateral and anterior canals, utricle, and a part of the saccule, whereas the inferior vestibular nerve innervates the posterior canal and most of the saccule. Due to this semicircular canal innervation pattern, complete functional loss from all three canals on one side suggests a complete vestibular neuritis involving both the superior and inferior vestibular nerves (Fig. 3b). Horizontal and superior canal deficits suggest superior vestibular neuritis (Fig. 3c), while posterior canal deficit alone suggests inferior vestibular neuritis (Fig. 3d) (Aw et al. 2001).

Other Assessments of Semicircular Canal Function

The HIT is useful for measuring individual semicircular canal function after medical intervention. Benign paroxysmal positional vertigo is due to lithiasis whereby misplaced otoconia inappropriately stimulate hair cells in response to changes in head position. It is most common in the posterior

Vestibular, Canal Testing: The Head Impulse Test, Fig. 3 Comparison of the head impulse tests from (a) normal subject with three vestibular neuritis (VN) patients; (b) left complete VN with horizontal, superior, and

posterior canals deficits; (c) left superior VN with horizontal and superior canal deficits; and (d) left inferior VN with only posterior canal deficit

canal but also occurs in horizontal and anterior canals. Surgical canal occlusion has been used to treat intractable disease that is not relieved by particle repositioning maneuvers. Superior canal dehiscence is a bony defect in the superior canal roof, leading to hypersensitivity of the vestibular and cochlear receptors to sound and raised middle ear or intracranial pressure. Surgical superior canal plugging or canal reroofing has been used to treat the condition. The HIT is important for assessing the semicircular canal's functional status after surgery. The occluded semicircular canal will show a positive HIT, but superior canal reroofing will preserve the superior canal function.

HIT can also be used to assess any unintended injury to the canals in surgical interference of the labyrinth such as in cochlear implantation, which has been shown to carry a low risk of destruction of semicircular canal function. HIT provides a quantitative index of individual semicircular canal functional ablation following intratympanic gentamicin (Carey et al. 2002) for partial ablation of canal function or selective vestibular neurectomy with preservation of hearing for Meniere's disease. Parenteral gentamicin is a cheap and effective antibiotic for life-threatening gram-negative infections with the rare but potentially devastating risk of vestibulotoxicity.

The HIT can clinically monitor the development of vestibular hypofunction by visually detecting the refixation saccade or quantitatively tests for any development of bilateral vestibular hypofunction.

School of Psychology, University of Sydney,
Sydney, NSW, Australia

Detailed Description

Why Measure Eye Movements to Test the Vestibular System of the Inner Ear?

Clear vision requires a stable image on the retina. However during normal everyday activities there are considerable head movements and so to provide a stable retinal image during head movements there has to be a mechanism to stabilize the eye. Receptors in the vestibular (balance) system of the inner ear detect head movement because head movements cause fluid flow in the semicircular canals of the inner ear resulting in receptors being activated. Neurons from those receptors drive the eyes via short fast pathways and act to correct for the head movement. In healthy people the eye movement is equal and opposite to the head movement so the image on the retina of the eye is stable and visual perception is clear. This process is called the vestibulo-ocular reflex (VOR). So while jogging it is possible to read signs because the vestibular receptors correct for head movements and provide stable gaze, or in other words, stable eye position in space.

Patients with vestibular disorders complain of *visual* problems as their head moves. So they report that during head movements their vision is blurred or bouncing (bouncing vision is called

“oscillopsia”) and to many of these patients it seems as if there is something wrong with their eyes. It is not their eyes but the vestibular system of their inner ear which has the problem. Their inadequate vestibular function means their eye movement correction for head movement is incomplete so their gaze is not stable - the image of the world is smeared across the retina during head movements and such retinal smear causes the subjective experience of blurred or bouncing vision and is unpleasant.

The direct short very fast neural transmission from the vestibular receptors to the eye muscles has led to the use of the eye movement response to head movements to provide a measure of the functional status of the vestibular sense organs of the inner ear. One such test of vestibular function is the eye movement response to small unpredictable passive head movements – this is called the head impulse test. Initially this was just a clinical test relying on the clinician to move the patient’s head and (subjectively) observe the eye movement response. More recently objective measures of the eye movement have become available as is explained below.

The clinical head impulse test (HIT) consists of the clinician facing the patient and holding the patient’s head at arm’s length and then turning the patient’s head with a small abrupt unpredictable horizontal head turn of about 10–20° to the left or right in less than 0.5 s while the patient is asked to keep staring at the tip of the clinician’s nose. Such a head turn is called a *head impulse*. Although it is small and very brief this kind of abrupt passive unpredictable head rotation has a peak angular velocity of around 200°/s and a peak angular acceleration of about 2500–3000°/s/s. These numbers sound enormous but they are simply the values of head velocity and acceleration encountered in everyday activities – for example turning your head to the left or right to check traffic while driving. In healthy subjects this brief passive head turn results in a short latency (about 10 ms) smooth compensatory vestibular eye movement response which compensates for the head movement so that the person’s gaze remains fixed on the target irrespective of whether the head turn is to the left or right. The eye

movement is equal and opposite to the head movement –so in healthy subjects it is said that VOR gain is close to 1.0. (VOR gain is a measure of the performance of the whole system from receptors to response and is defined as the ratio of eye velocity to head velocity.) (Halmagyi and Curthoys 1988; Halmagyi et al. 1990).

For a patient with unilateral loss of vestibular function (UVL) the result on the HIT is very different. If the patient’s head is passively but abruptly turned to their healthy side the VOR gain is about the normal value or only modestly reduced. But if the patient’s head is passively turned towards their affected side there is a marked reduction in VOR gain. The eye velocity does not match the head velocity and so the visual image is smeared across the retina. As a result at the end of the head turn the patient will not be looking at the target but somewhere over to the same side as the head has turned because the eye has been dragged with the head off the target. So to obey the instructions to keep looking at the target the patient must make a rapid corrective eye movement – a saccade - back to the target and that corrective saccade at the end of the head turn is what the clinician sees. It is the “tell-tale” sign of inadequate vestibular function. In many patients repeating the head turns a few times shows the affected side clearly.

Why is HIT such a specific test of semicircular canal function? Because the response is *too early* for other eye movement control mechanisms to be able to generate the appropriate eye velocity to correct for the head rotation. This has been shown by measuring the responses of patients with known vestibular loss due to surgery. In such patients all the other sources of eye movement control – such as volition, visual and neck input - are all functional but the vestibular input is not. The results show that the earliest part of the eye movement response to brief unpredictable passive head angular acceleration is inadequate. There is simply not enough time for other oculomotor control systems (such as vision or volition) to operate. The early response is purely vestibular. So this very simple head turn stimulus is a very effective way of probing vestibular function specifically free of visual neck or cognitive control

(Halmagyi and Curthoys 1988; Halmagyi et al. 2003).

However it has been shown that some patients with vestibular loss can generate the corrective saccade *during* the head turn itself so there is no tell-tale “overt” saccade at the end of the head turn and so the clinician wrongly concludes the person has a healthy vestibular system. Such a corrective saccade occurring during the head turn is called a *covert saccade* in contrast to the *overt saccade* at the end of the head turn. It is called “covert” because the clinician cannot detect it by the naked eye.

The way around this significant problem is to obtain *objective measures* of the eye movement during the head movement. This is not a trivial exercise but it is what the video head impulse test (vHIT) does. By using a lightweight very fast video camera in goggles securely attached to the head it is possible to measure accurately the eye movement during the head movement (MacDougall et al. 2009; Fig. 1). Sensors embedded in the goggles measure the head movement. The video head impulse test is able to quantify the VOR quickly accurately and *objectively* and show objectively the presence of covert or overt corrective saccades (Weber et al. 2008). In particular covert catch-up saccades are readily detected by this technology. The vHIT test has been validated against the research gold standard for eye movement measurement - the magnetic scleral search coil technique – by comparing simultaneous measures of the same eye in healthy subjects and patients by both search coil and video methods and the results are almost identical (MacDougall et al. 2009).

Vestibular, Eye Movement Testing, Fig. 1 A close up view of the head mounted camera system for the vHIT

Notice that this simple example has shown you that there are basically two types of eye movements involved in vestibulo-ocular response – relatively slow compensatory eye movements and very rapid ballistic movements (saccades).

How Does vHIT Work?

The image of the eye is usually reflected from an infra-red reflecting mirror (a “hot” mirror) into a side-mounted or top-mounted lightweight camera attached by a tight strap to the subject’s head. In this way the subject can see visual stimuli through the hot mirror whilst the image of the eye is reflected from the mirror and recorded by the camera. Improvements in camera and computer technology have transformed this area so that now very small lightweight high speed, high resolution cameras are readily available. And fast computers running fast software have transformed the once demanding task of measurement of eye movement into a simple process. Development of a lightweight head-mounted camera and software system which measures the eye movement and the head movement at high speed and with great accuracy quantifies the vestibulo-ocular response (VOR) (MacDougall et al. 2009). Below are records from vHIT testing of a healthy subject. There are three graphs. The larger two show the superimposed time series records of the head velocity stimulus and the eye velocity response for every head turn. The graph on the left shows the result for leftwards head turns testing the left horizontal canal and the graph on the right shows the results for rightwards head turns testing the right horizontal canal.

In all cases the records have been aligned to the onset of the head movement. Head velocity (blue traces) and eye velocity (orange traces) are superimposed so that even small but systematic deviations in eye velocity response can be seen. The eye velocity records have been inverted to show how closely the eye velocity matches and thus compensates for head velocity. The summary figure at the left shows the VOR gains for rightwards (open circles) and leftwards head turns (filled circles) for every single head turn in both directions. As is

Vestibular, Eye Movement Testing, Fig. 2 Records from vHIT testing of a healthy subject. There are three graphs. The larger two show the superimposed time series records of the head velocity stimulus and the eye velocity response for every head turn. The graph on the *left* shows the result for leftwards head turns testing the *left horizontal* canal and the graph on the *right* shows the results for rightwards head turns testing the *right horizontal* canal. In all cases the records have been aligned to the onset of the head movement. Head velocity (*blue traces*) and eye velocity (*orange traces*) are superimposed so that even

small but systematic deviations in eye velocity response can be seen. The eye velocity records have been inverted to show how closely the eye velocity matches and thus compensates for head velocity. The summary figure at the left shows the VOR gains for rightwards (*open circles*) and leftwards head turns (*filled circles*) for every single head turn in both directions. As is clear from the raw data and the VOR gains (around 1.0) this person has normal VOR for both directions of head rotation so we can infer that horizontal semicircular canal function is normal on both sides

clear from the raw data and the VOR gains (around 1.0) this person has normal VOR for both directions of head rotation so we can infer that horizontal semicircular canal function is normal on both sides (Fig. 2).

There are some (very small) overt saccades (the “stalagmites”) after the head turns. Healthy people have overt and occasional covert saccades during head impulse testing but they are usually very small and infrequent. The important thing is not the occurrence of a few small saccades but whether the saccades occur in combination with the reduced eye velocity during the head impulse. Here the VOR gain is obviously excellent so the tiny saccades have no clinical significance. With patients the saccades are large as the next example shows (Fig. 3).

Safety

Video systems for recording eye movements have the advantage that they are non-invasive – no

electrodes are attached to the person. The video goggles are simply worn much as any normal goggles are worn. The level of infra-red illumination is very low and far below the internationally agreed infra-red hazard criteria (Delori et al. 2007). The goggles can be worn for long periods without discomfort or danger to eye health. The actual movement of the head is very small, smaller than carried out by physiotherapists or chiropractors.

Slippage

If the camera moves relative to the eye – if it slips on the head – then the system erroneously records that slippage as an eye movement since the image of the eye moves across the camera plate. Since the whole eye movement during a head impulse is very small the camera only needs to slip by a very small amount to cause a big measurement error. Trying to get acceptable eye movement data from large relatively heavy camera/goggles just does not work.

Patient with right unilateral vestibular loss

Vestibular, Eye Movement Testing, Fig. 3 Comparable vHIT results from a patient who had a unilateral vestibular loss on the right side as shown very clearly by the reduced slow-phase compensatory eye velocity – so the VOR gain for rightwards head turns is about 0.3 (rather than 1.0) complemented by the overt and

covert saccades for rightwards head turns. The saccades which occur while the head is still moving as opposed to after the end of the head movement, are called covert saccades. They would be extremely difficult to detect by the naked eye. The low VOR gain is confirmed by the presence of the saccades

The Video Camera

The camera *must* be high speed. The vHIT cameras acquire images much faster than standard video cameras – at around 250 frames/s – whereas standard video camera frame rate is about 30–60 frames/s. Obviously to measure a moving eye speed is important. And saccades (overt and covert) are the very fastest eye movements there are and they only last a very short time so a very fast camera is needed to catch them. We know that 60 frames/s is too slow to give accurate measures of saccades and VOR and that 250 frames/s does give accurate measures. We know this from direct comparison of fast and slow cameras on the same patient - low speed cameras miss or greatly reduce the saccades. So in one patient at low camera speed the eye movement of the patient with known unilateral vestibular loss looked normal but with the high speed camera the unilateral loss was clear both because of the reduced VOR gain and also the confirmatory covert saccades which the high speed camera detected but the low speed camera missed. Direct comparison of a video camera with a 250 Hz frame rate to scleral search coils at 1000 Hz sampling rate showed there was no systematic difference in measured

eye velocity so we deem that video data acquired at 250 Hz is acceptable.

The camera must be high resolution. The image of the eye is small and the total movement of the eye during a head impulse is small – just a few degrees – so a camera with inadequate resolution will not be able to detect these small eye movements accurately. Similarly the image of the eye should be sharp since a blurred image will sacrifice accuracy.

Acquisition and Geometry

Underlying all the data analysis is a robust well defined geometrical coordinate frame since the mathematics of eye rotations are not trivial (Haslwanter 1995). Usually the eye movement is derived from finding the pupil centre and tracking that centre relative to the head-fixed camera. So it is imperative that the image of the eye be of sufficient quality to allow an accurate determination of the pupil centre. Even with the coordinate frame a geometric correction is needed because the eye movement is measured from the image of a three dimensional sphere projected onto a two dimensional plane (Moore et al. 1996).

Acquisition to computers is presently by high speed fire-wire or USB 3 systems. After the centre of the pupil is found and tracked the data analysis requires filtering and differentiating to yield eye velocity. Parameters in filter order, filter cut-offs and differentiator characteristics all influence the actual measured eye velocity.

Calibration

In order to measure eye velocity the system needs information about the size of the signal caused by an eye rotation through a known angle. The usual calibration is two spots on the wall located a known distance apart and the patient has to look at each in turn and the computer logs that data and uses it to calculate eye velocity. If there is an error here then all the eye velocity measures will be in error and so the VOR gain calculations will be in error.

Practical: The Video Head Impulse Test

The operator stands behind the patient with their hands on the patient's head but away from the goggle strap. The operator aims to turn the head to the left or right *unpredictably* through a small angle – about 10–20° is ideal. It is not necessary (or advisable) to make large head turns. The important part of the test is what the eye does at the very early part of the head turn so the key is to make the start of the head turn abrupt – a small abrupt head turn is ideal. The ideal head impulse is “turn and stop”. There should be as little overshoot (or rebound) as possible.

Each head turn is a separate test of vestibular function of the semicircular canal on the side to which the head is turned. Each extra head turn just repeats the test and this is valuable for providing increased clinician confidence about the functional state of the canals.

Active head impulses where the patient turns their head voluntarily do not reveal the VOR deficit (Black et al. 2005) probably because the patients who actively generate the head turn can also actively generate covert saccades.

Testing the Vertical Semicircular Canals

If one attempts to turn the head in the plane of the vertical canals (which are about 45° to the median plane of the head) with head facing forward and gaze centrally located then it is necessary to measure ocular torsion (at high sampling rates) because the eye movement response to these diagonal head movements has a vertical and a torsional component. (Torsion is rotation around the line of sight.) High speed accurate measures of torsion are computationally expensive and so time expensive. Moving the patient's head in these planes whilst the patient faces straight ahead is awkward for the operator and uncomfortable for the patient.

Both of these problems can be overcome if prior to the first impulse the patient's head is turned on their shoulders so that their nose faces 30° to the left or right of their body median plane. Then pitching the head forward and back *in the body median plane* is relatively straightforward and tests the vertical canal response by measuring the vertical eye velocity component (MacDougall et al. 2013a, b). The head pitch is in the median plane of the body but it is aligned with the vertical canals in the (turned) head. So head pitches like this activate the vertical canals and elicit corrective eye movements which are mainly vertical (no torsion). So simple fast computer algorithms can be used to measure the eye movement response and calculate VOR gain of the vertical semicircular canals (Curthoys 2012).

VOR Gain

VOR gain is a performance indicator taken at one point in time or over a narrow time window. VOR gain is defined as the ratio of eye velocity to head velocity and it arose from an engineering analysis of the response to sinusoidal rotation stimuli. The value of VOR gain can vary from 0 (with no compensatory eye movement) up to values of 1.0 and greater. Perfect compensatory eye movements have a gain of 1.0 where eye velocity is equal and opposite to head velocity. But the question becomes – *which* value of head velocity

should be used for this calculation? In the past the VOR gain has been calculated using eye velocity at peak head velocity. It has become very clear that trying to quantify this entire complex vestibular-elicited response by a single number is a very inadequate representation of performance. For example, some patients to an abrupt head turn show an initial high-gain vestibular-driven response early which rapidly decays as the head turn continues – so VOR gain may be well above 1.0 at the start and well below 1.0 at the end of the response. For the present, VOR gain will continue to be used since it is so widely understood but VOR gain has severe inadequacies and improved metrics of performance will be a focus of future research.

Why is the gain not exactly 1.0? Textbooks give the impression that the VOR should be exactly 1.0. In fact this is very rarely true. Perfectly healthy people who have no symptoms of visual blur or oscillopsia can have gains much smaller than 1.0 (0.85 or less) or gains much higher (1.2 or more). These people do not complain of blur or oscillopsia during head movements. Why? There are probably a host of reasons. One is that wearing spectacles modifies the VOR gain even when the spectacles are removed.

Repeatability

VOR gain is not necessarily constant in patients from day to day – it has been shown in early Ménière's Disease patients that there are fluctuations in VOR gain from occasion to occasion especially around the time of the attack (Manzari et al. 2011). These fluctuations are almost certainly occurring because of the changes within the membranous labyrinth.

Historical Note

Up to 1987 the tradition for vestibular testing was to deliver slow sinusoidal rotations (0.2–1.0 Hz) and measure the eye movement response. That tradition was overturned when it was shown that a patient with no semicircular canal function

following bilateral surgical vestibular nerve removal could still generate compensatory eye movements to such predictable low frequency sinusoidal stimuli (Halmagyi and Curthoys 1988; Halmagyi et al. 1990). However this patient with bilateral vestibular loss could not generate compensatory eye movement response during the first 100 ms of an unpredictable high acceleration head turn. As a result the modern approach to testing vestibular function has been to deliver natural values of angular acceleration using the safe means of the operator's hands – but to *measure* the stimulus exactly and to relate the response to that stimulus. This has proved to be a very effective way of quantifying the VOR and identifying deficits.

Central Problems

It is important to be aware that using eye movement in response to head movements to indicate peripheral vestibular dysfunction rests on the assumption that the neural pathways from the inner ear to the eye muscles are functioning correctly. Clearly if there are deficits in pathways from the vestibular nuclei to the oculomotor nuclei the eye movement response will be affected. For example, demyelination of axons in patients with multiple sclerosis reduces the transmission speed of central neurons so there are clear delays in the eye movement response even though the peripheral vestibular function is normal.

Transmission of the neural signals is under the control of two major control systems: the cerebellum and the reticular formation. Cerebellar inhibition can modulate the neural transmission from the inner ear to the eye muscles even silencing it entirely so that as the head moves there is no compensatory eye movement response (Robinson 1976). Or reduced cerebellar inhibition can enhance that transmission so that the eye movement response more than compensates for the head movements (the VOR gain is then greater than 1.0). Cerebellar inhibition suppresses the VOR so it is possible to read a newspaper on a bus as it goes around a corner – the eyes are not reflexively driven off the page by the angular

stimulation but thanks to the cerebellum remain on the page even though the semicircular canals are being activated by the turn. Another source of control comes from the nuclei in the brainstem - the reticular formation where alertness can cause profound changes in the eye movement characteristics – reducing slow phase eye velocity and slowing saccades in drowsiness or drunkenness.

Vestibular, Rehabilitation

Michael C. Schubert

Department of Otolaryngology Head and Neck Surgery, Johns Hopkins University School of Medicine, Baltimore, MD, USA
Department of Physical Rehabilitation and Medicine, Baltimore, MD, USA

Definition

The vestibuloocular reflex (VOR) has been created with an amazing plasticity that counters the inevitable forces of disease and aging that barrage the reflex. In fact, this plasticity prevents us from suffering significant functional impairments – namely, gaze and gait instability. One example of the critical and extreme plasticity within the VOR includes complete reversal of the VOR when fit with lenses that demand it. The three primary functions of the peripheral vestibular system are (1) stabilizing visual images on the fovea of the retina during head movement to allow clear vision; (2) maintaining postural stability, especially during movement of the head; and (3) providing information used for spatial orientation. The purpose of this article is to outline how vestibular rehabilitation must incorporate head rotation in order to improve gaze and gait instability due to a deficient VOR.

Detailed Description

Semicircular Canals

Within the petrous portion of each temporal bone (base of the skull between the sphenoid and occipital bones) lies the membranous vestibular labyrinth. Each labyrinth contains five neural structures that detect head acceleration: three semicircular canals and two otolith organs. For this article, emphasis will be the semicircular canal anatomy and physiology. The three semicircular canals (SCCs) (horizontal, posterior [inferior], and anterior [superior]) respond to angular acceleration and are orthogonal with respect to one another. Alignment of the SCCs in the temporal bone is such that each canal has a contralateral coplanar mate. The horizontal canals form a coplanar pair while the posterior and contralateral anterior SCCs form coplanar pairs. The anterior aspect of the horizontal SCC is inclined 30° upward from a plane connecting the external auditory canal to the lateral canthus. The posterior and anterior SCCs are inclined about 92° and 90°, respectively, from the plane of the horizontal SCC (Della Santina et al. 2005).

Because of this alignment in the head, the SCC can detect rotational head velocity in any combination of directions (yaw, pitch, roll). The SCCs are filled with endolymph (fluid) that has a density slightly greater than water (Smith et al. 1954). Endolymph moves freely within each canal in response to the direction of the angular head rotation. The SCCs enlarge at one end to form the ampulla. Within the ampulla lies the cupula, a gelatinous barrier that contains the sensory hair cells. The kinocilia (mechanosensing cilia involved in the sense of movement) and stereocilia (mechanosensing organelles) of the hair cells are seated in the crista ampullaris (sensory organ of angular rotation). Deflection of the stereocilia caused by motion of the endolymph results in an opening (or closing) of the transduction channels of hair cells, which results in changes in the membrane potential of the hair cells. Deflection of the stereocilia toward the kinocilia in each hair cell leads to depolarization and deflection of the stereocilia away from the

kinocilia leads to hyperpolarization. As a result of this sensory hair cell anatomy, the SCCs have a dual sensory and motor function.

Abnormal SCC Function and Abnormal Gait

Postural and gait instability can result from semicircular canal hypofunction. This instability is typically related to a hypermetric postural response that occurs when posture is challenged. Measures of acceleration reveal an age-related inability to attenuate head acceleration during postural perturbations and gait. In contrast, healthy younger controls can reduce joint acceleration for the head (and upper trunk) even as their walking speed increases (Kavanagh et al. 2004; Latt et al. 2008). In vestibular hypofunction, a greater than normal amount of head (and gaze) oscillation occurs when subjects make active head rotations – suggesting head motion instability (Lehnen et al. 2009). Additionally, patients with vestibular loss have more irregular head and whole-body velocity trajectories (Lafond et al. 2004). These pathomechanical changes may be a direct result of the loss of vestibular afferents (due to age and disease) onto Purkinje cells or direct damage to the central vestibular pathways thereby releasing the normal inhibition of central vestibular neurons mediating the vestibulospinal tract resulting in postural instability and an increased fall risk.

Few studies have examined SCC hypofunction and parameters of balance. In postural studies, static center of pressure (COP) refers to an excursion trace that identifies the location of the resultant ground reaction forces from the feet (Lafond et al. 2004). When the COP sway excursion or velocity is greater, balance is worse. COP velocity is greater in patients with SCC hypofunction compared with control subjects (Krebs et al. 1993; Crane and Demer 1998; Sevilla-Garcia et al. 2009). In SCC hypofunction, gaze and COP velocities are correlated – as gaze velocity increases, so does center of pressure velocity (Crane and Demer 1998). In addition, patients

with abnormal semicircular canal function have greater gaze velocity during tilt than control subjects (Crane and Demer 1998). Recent studies measuring gaze stability during balance perturbations show an inverse correlation between gaze fixation and latency to step (Diehl and Pidcoe 2010).

Based on canal-mediated (and otolith-mediated) compensatory eye rotations that stabilize gaze (vision) during both passive whole-body rotation and ambulation, Crane suggested a model that illustrated that cues such as proprioception, motor efference copy, and prediction were not important to the generation of compensatory eye movements during ambulation (Crane and Demer 1999). It remains impractical, therefore, that optimal VOR function rely on proprioception, prediction, or even visual feedback during ambulation since latencies from these systems would at best be 80 ms – well above that of the VOR (Carl and Gellman 1987; Bronstein and Gresty 1988; Lisberger 1990; Crane and Demer 1997). Evidence therefore suggests that gaze stability and VOR gain (eye velocity/head velocity, ideally the gain is equal to unity during typical viewing) correlate with balance, which indirectly implies that SCC excitation through VOR gain adaptation exercises may improve the vestibulospinal response of patients. This has not been directly verified.

Abnormal SCC Function and Abnormal Dynamic Visual Acuity

Dynamic visual acuity (DVA) refers to the ability to see clearly during head rotation. DVA therefore is a functional measure of SCC function and other mechanisms of gaze stability the brain may recruit. Patients with abnormal SCC function (unilateral and bilateral) have been found to have improved DVA only when performing VOR adaptation exercises compared with placebo exercises (Herdman et al. 2003, 2007). The strategy the brain uses to improve DVA appears to be increasing the gain of the VOR and recruiting a unique type of saccade that occurs in the same direction of the deficient VOR (Schubert et al. 2008).

Role of Vision and Head Motion in Recovery from SCC Deficit

Two sensory stimuli are required for significant adaptation of the VOR: vision and head motion. Traditionally, adaptation paradigms designed to enhance the gain of the VOR have been done with short-term (less than 1 h) or long-term (greater than 1 day) time exposure. A number of VOR adaptation studies have demonstrated a robust capability for changing the normal VOR by coupling head motion with target motion. When the viewed targets move in such a manner that the image slips on the retina, the VOR is recalibrated. The direction of the recalibrated VOR (increased or decreased gain) depends on the direction of the target motion in relation with the head motion. During head rotation, visual following of targets that move at a velocity different from the head rotation will create an adaptation (change) in the gain of the VOR. This is commonly achieved by 1 of two means: (1) targets are viewed wearing lenses that magnify the visual world (increases target velocity) or minimize the visual world (decreases target velocity); (2) targets are viewed that move in a direction opposite the head rotation (increases target velocity) or move in the same direction of head rotation (decreases target velocity). The difference between the target velocity and the eye velocity is termed retinal slip and can be quantified. Retinal slip is therefore a velocity error signal, thought to be the most effective means for changing VOR behavior, e.g., VOR gain (Ito 1982; Eggers et al. 2003).

Clinical experience suggests that some patients with vestibular hypofunction adopt a strategy of avoiding rapid head rotations toward their lesioned side, thereby reducing retinal slip but perhaps also missing an opportunity to generate a retinal slip stimulus that would otherwise drive VOR compensation (Herdman 1998; Cromwell et al. 2004; Kvåle et al. 2008). Reducing this gaze error through vestibular rehabilitation appears to improve gaze stability (Schubert et al. 2008, 2010).

Vestibular, Rehabilitation, Fig. 1 Times one VOR adaptation exercise. The patient is instructed to keep the target (letter X) still and in focus while moving the head *left to right* (and separately *up* and *down*). The speed of the head rotation depends on the clarity of the target. If the target blurs or appears to move, the patient should be instructed to slow down. *Arrows* denote head rotation

VOR Adaptation Exercises

The purpose of adaptation exercises is to improve the VOR and other systems that are used to assist gaze stability. VOR adaptation exercises are designed to expose patients to retinal slip. Because the brain can tolerate small amounts of retinal slip without perceiving image instability, the patient should be instructed to keep the target in focus. Otherwise, head motion that is too rapid will result in excessive retinal slip. The two primary VOR adaptation exercises are $\times 1$ (times 1) and $\times 2$ (times 2). In the $\times 1$ exercise, the patient is asked to move the head horizontally (and separately, vertically) as quickly as possible while maintaining focus on a stable target (Fig. 1).

The patient must learn to slow the head movement if the target becomes blurred. A good target to use is a business card, asking the patient to focus on a word or a letter within a word. The exercise can be modified in many ways: (1) changing the target distance (i.e., near and far), (2) providing a busy visual background while the patient attempts to keep visual focus on the target during

Vestibular, Rehabilitation, Fig. 2 Times two VOR adaptation exercise. The patient is instructed to keep the target (letter X) in focus while moving the head and target in opposite directions. The speed of the head rotation depends on the clarity of the target. If the target blurs or appears to move, the patient should be instructed to slow down. *Thick arrows* denote head rotation. *Thin arrows* denote target motion

head motion, and (3) doing the exercise while walking. The $\times 2$ paradigm requires the patient to move the head and target in opposite directions (Fig. 2).

Conclusion

Vestibular adaptation exercises are an excellent starting point for rehabilitation of patients with semicircular canal deficits (i.e., vestibular hypofunction). Research supports the beneficial effects of vestibular adaptation exercises on gait, posture, and visual acuity.

Definition

An electronic system, usually comprised of external and implanted components, that can sense light, convert light to an electronic signal, and apply that signal to the retina, as a treatment for blindness secondary to photoreceptor loss.

Detailed Description

In a healthy retina, light is detected by photoreceptors (rods and cones) via photosensitive molecules in the outer segments of the photoreceptors. These molecules, once transformed by light, trigger a cascade of neurochemical events that lead to other neural cells in the retina (ganglion cells), sending signals to the downstream visual centers of the brain. Retinal degenerative diseases, like retinitis pigmentosa and age-related macular degeneration, affect primarily photoreceptors, leaving the retina unable to sense light, but remaining neurons in the retina (bipolar cells and ganglion cells) can be electrically activated, based on established techniques for nerve stimulation.

A typical retinal prosthesis has multiple components each with a specific function (Fig. 1). These include an imager to convert light to electrical signal, electronics to process and condition the image and generate electrical stimulus pulses,

and an array of microelectrodes to stimulate the retina. Other important components found in one form or another on most implants include hermetic packaging and wireless data/power transmission. However, retinal prostheses are often categorized based on the location of the electrode array, which forms the functional interface with the retina. The locations where an electrode array can be implanted to stimulate the retina include epiretinal (on the top surface of the retina), subretinal (under the retina), and suprachoroidal (between the sclera and choroid).

Several prototype systems of chronic implantable devices have been tested in clinical trials. These fall into two types of implants. The first type of device was designed to show feasibility in humans, but not intended to be a commercially viable medical device. Thus, the main concern for these devices was patient safety, and they generally were not refined to the same degree as a commercial product. For example, a number of

Vision Prosthesis, Fig. 1 Retinal prosthesis concept – an external camera captures an image. Wireless transmission of image data to an implant specifies the stimulation pattern that is applied to the retina via a microelectrode array

these early chronic implants could only be activated when the patient visited the clinic. The second type of devices are intended as commercial devices, so they are engineered not only for robustness and safety but also for expected longevity of over a decade and with human factors considerations. One device, the Argus II retinal prosthesis (Second Sight Medical Products, Inc.), has received approval in both Europe and the United States to be sold as a treatment for retinitis pigmentosa. A summary of current and past clinical trials of retinal implants can be found at www.clinicaltrials.gov; search “retinal prosthesis.”

Epiretinal implants involved in feasibility studies include the Argus I from Second Sight and devices from Intelligent Medical Implants, GmbH (IMI), and the Epi-Ret Consortium (Epi-Ret). All three of these systems used wireless power and data delivery (to avoid transcutaneous wires).

The Argus I device was implanted in six subjects between 2002 and 2004 (de Balthasar et al. 2008). Argus I was a modified cochlear implant. As such, the electronics were implanted behind the ear and a cable run along the temple, into the orbit, and, finally, into the eye, terminating in a 4×4 grid of platinum electrodes, either 520 or 260 mm diameter. With training, subjects were able to distinguish objects from a small set and detect motion of a moving bar. Subjects have been implanted for as long as 8 years with the device still functional.

The IMI device was implanted in a total of seven subjects (Hornig et al. 2007). This device utilized a microfabricated array with a total of 49 electrodes. The implant was entirely in the orbit, with the electronics module on the outside of the eye and the electrode array in the eye (via a cable across the eye wall). This system could only be activated in the clinic as no camera system was available. Using this device, subjects could see spots of light and some simple patterns. Since the electronics were not hermetically packaged, but only sealed with polymer coatings, the implants were removed after several months or, in one case, 1.5 years.

The Epi-Ret device was implanted in six patients (Klauke et al. 2011 Jan). The stimulating array had 25 electrodes and also was miniaturized to the point where the entire device could be

implanted in the eye. A unique feature of the stimulating array was protruding electrodes, which improved contact with the retina and resulted in low perceptual thresholds. Like the IMI device, the Epi-Ret system was designed only for semi-chronic implantation (4 weeks) and did not have a camera system so the implant could only be activated in the clinic.

Commercial Design

Approval to sell a medical device as a treatment for a specific disease is only granted after approval by government agencies. The Argus II epiretinal prosthesis has received approval in Europe and the United States. The Argus II is similar to the IMI device, in that the electronics are on the outside of the eye and the electrode array is on the retina, connected by a cable across the eyewall to the electronics (Humayun et al. 2012). The Argus II, however, has a camera system that provides input to the implant, and the electronics are protected with a hermetic package, so that implant longevity is decades. Thus, patients with implants can leave the clinic with the system. Sixty electrodes are arranged in a 6×10 format.

Thirty subjects were enrolled between 2007 and 2009. All subjects were able to perceive light during electrical stimulation. Other tasks on which subjects performed well include object localization and motion detection. Letter reading was tested in 22/30 subjects (da Cruz et al. 2013). Six of these subjects were able to identify any letter of the alphabet at a 63.5% success rate (vs. 9.5% with the system off). In all 22 subjects, a small set of eight letters was identified 72.5% correctly vs. 16.8% with the system off. Subjects were free to take as much time as needed to make a judgment. Adverse events that occurred during the trial included low eye pressure and infection, but such events decreased in later implants.

Conclusion

Epiretinal prostheses have proven that they have the capability to improve the lives of people blind

from retinal degenerative disease. Multiple systems have been tested in humans, with one device receiving approval for sale.

Definition

Visual aftereffects are systematic changes in perception of a visual stimulus after adaptation to a previous stimulus. For instance, the tilt aftereffect affects the perception of tilted lines – after staring

at an oriented line, slightly rotated lines appear to be much more different in orientation. Similar effects occur for a very wide variety of stimuli and have prompted a range of computational explanations primarily focusing on changes in responsiveness of feature-selective neurons in the visual cortex. Aftereffects are one type of visual illusion, which are discussed further in the entry.

Detailed Description

Visual aftereffects have been described for an extremely wide range of visual stimuli in a variety of contexts. A well-studied example is the motion aftereffect, which was originally reported (somewhat ambiguously) by Aristotle and has been independently rediscovered many times since. One of the most influential descriptions of this effect, also known as the waterfall illusion, is from Robert Addams in 1834 (Fig. 1).

After extended exposure to a pattern moving in one direction (such as a waterfall), viewing a roughly similar but static pattern (such as an adjacent rocky cliff) produces a sensation of motion in the opposite direction. Here the moving stimulus is called the adaptation pattern (to which the visual system becomes adapted), and the static pattern is called the test stimulus. No effect is seen without a suitable test stimulus.

In the tilt aftereffect (Gibson and Radner 1937), adaptation to lines of one orientation changes the perception of subsequent test lines differing in orientation. Specifically, test lines slightly rotated from the adaptation pattern appear shifted in orientation in a direction away from that of the adaptation pattern (though not opposite, as in the motion aftereffect), while test lines very different in orientation are perceived as being slightly more similar to the adaptation pattern's orientation (Fig. 2).

Similar direct and indirect effects have been found for the motion direction aftereffect, which is a variant of the motion aftereffect that uses moving test stimuli of various orientations (Schrater and Simoncelli 1998). Other aftereffects involve further levels of complexity. For instance,

Visual Aftereffects, Models of, Fig. 1 Motion aftereffect. While visiting this waterfall (the Falls of Foyers, near Loch Ness, Scotland), Robert Addams watched the falling water for some time. He then looked over to the adjacent rock face and noticed that the rocks appeared to be moving upward. He was later able to replicate this effect mechanically using a visual pattern drawn on a moving belt, which helped make the phenomenon suitable for scientific study (Photo © 2000, James A. Bednar)

in the McCollough effect (McCollough 1965), viewers perceive orientation-specific changes in color of a black and white test stimulus, after exposure to multiple-oriented colored lines (Fig. 3).

Many other aftereffects have been reported, such as various types of face aftereffects (e.g., changes in perceived gender of androgynous stimuli after exposure to a male or female face; Leopold et al. 2001; Zhao et al. 2011) and even blur aftereffects (changes in perceived blur after exposure to a certain level of sharpness or blurriness). See Thompson and Burr (2009) and Webster (2012) for reviews of additional types of aftereffects.

Aftereffect Mechanisms

Over the centuries, a wide variety of explanations have been offered for the various effects. For instance, Addams' explanation for the movement aftereffect was in terms of entrained eye movements, though this was later disproved by showing that the effect is specific to an area of the retina. After neurons selective for visual features were discovered in the primary visual cortex in the 1960s, explanations began to focus on adaptation (changes in the responsiveness) of these neurons over time. A common assumption was that "if you can adapt it, it's there" (Mollon 1974), suggesting that behind each aftereffect

Visual Aftereffects, Models of, Fig. 2 Tilt aftereffect. If you look briefly at the set of lines in the middle and then look over to a blank area such as the margin, you are likely to see an afterimage, a simple type of aftereffect with a sensation of the same pattern but the colors swapped. To experience the tilt aftereffect instead, try staring at various locations inside the small circle, moving your eyes around

regularly to minimize the afterimages. After 30–60 s, look at the circle in the *left* (vertical) pattern. The vertical pattern should now look tilted slightly clockwise (the direct TAE). The horizontal pattern on the right may look slightly tilted anticlockwise, though this indirect effect is smaller and more variable and so not always noticeable

Visual Aftereffects, Models of, Fig. 3 McCollough effect. Before adaptation, the test pattern on the left should appear *black* and *white*. To reproduce the McCollough effect, stare alternately at the two colored patterns for 3 min, moving your gaze regularly to avoid developing

strong afterimages, and then look back at the *black* and *white* test pattern. *Vertical bars* should now be slightly tinged with *magenta*, and *horizontal bars* should be slightly tinged with *green*. The effect should reverse if you tilt your head 90° and disappear if you tilt 45°

lies a corresponding set of feature-selective cells undergoing adaptation.

For instance, negative color afterimages from looking at any bright pattern could be explained as adaptation of light-sensitive cells in the retina, perhaps interpreted mechanistically as depletion of some limited resource within a single cell, such as what occurs in cone pigment photobleaching. Most explanations of afterimages do focus on the retina, because afterimages are specific to retinal location and to each eye, which matches the properties of retinal (and thalamic) cells.

Explaining effects more complex than afterimages requires either more complex models incorporating additional areas of the visual system, more complex mechanisms for reading out the illusory percept from the neural activity, or both. For instance, many explanations for the motion aftereffect have been based on responses in two sets of motion-selective neurons, with opposite preferred directions of motion. If the perceived motion is the balance or average value of these two population activities, a movement aftereffect will be seen when one of the populations adapts more than the other (Fig. 4).

The opponent-code idea has been used to explain aftereffects for color and for various types of face perception, using an opponent axis of, e.g., red versus green, male versus female, or face versus anti-face (Webster 2012).

An alternative explanation is in terms of multichannel coding. Here, neurons are no longer

specifically separated out into opposing pools but instead represent a wide variety of different preferences, each characterized as narrow band-pass (e.g., bell-shaped) tuning. Each such neuron would adapt independently, and the net effect could be computed as some sort of population average or overall probabilistic estimate (Series et al. 2009). For instance, the motion aftereffect can be explained as changes in the average or net perceived direction of motion, across a wide-ranging population (Fig. 5).

Similar multichannel explanations could apply to other phenomena like the tilt aftereffect, based on orientation-selective cells in V1 (Bednar and Miikkulainen 2000).

Deciding between opponent and multichannel explanations can be complex. For instance, even though retinal ganglion cells are chromatically opponent, the underlying photoreceptors are still band pass in terms of wavelength, rather than responding more strongly to longer and longer wavelengths (e.g., infrared). Thus, color can also be considered a multichannel encoding, albeit with only a small number of channels. Similarly, motion direction is arguably a multichannel encoding despite any opponency that may be involved, because neurons with a very wide variety of motion direction preferences have been found (Weliky et al. 1996). Multichannel models have been able to explain the motion aftereffect and color aftereffects without any explicit implementation of opponent coding as a physical

Visual Aftereffects, Models of, Fig. 4 Opponent-code adaptation. Some aftereffects, such as movement and some kinds of color effects, can be described in terms of opponent processes between two pools of neurons. Here the population response (the total response to a stimulus of a given speed) is plotted for all the upward-preferring neurons (*dotted line*); these respond best to stimuli with a positive velocity (stimulus >0). Similarly, the *solid line* shows the population response of the downward-preferring neurons to each velocity; they respond best to negative velocities. For a given test stimulus, the perceived velocity would be calculated as some sort of average or net activation between these two pools. Before adaptation (*left*), both populations respond equally to a static (stimulus 0) test

pattern, and so the pattern would correctly be perceived as static. Similarly, after adaptation to a static pattern, responsiveness has decreased overall, but a static test pattern continues to be perceived correctly as static, since both populations have adapted similarly. However, after adapting to downward motion of speed 15 (in arbitrary units), the net population activity in response to a static pattern will tend toward upward motion (*right*). Here the central “norm value” is special in terms of defining the two opposing populations; aftereffect strengths will increase as adaptation patterns become more dissimilar to this norm and thereby more specifically activate one or the other of the two populations

Visual Aftereffects, Models of, Fig. 5 Multichannel-code adaptation. A multichannel model for the movement aftereffect might be based on neurons that are each selective for a specific direction of motion, such that many different direction selectivities are represented (here visualized as a set of direction tuning curves plotted along the x axis, with x being the motion direction angle in retinal space). The strength of each neuron’s response would be modulated by the stimulus velocity, such that each neuron responds only slightly to a static pattern. The perceived direction and speed of motion would be perceived as a population average of the responses of all the neurons, such that a moving stimulus will activate a small subset of these neurons strongly (thus having an average corresponding to a specific motion direction). A static

pattern would activate all of these weakly and equally, resulting in no net perceived motion direction. After adapting to, e.g., vertical motion (stimulus 0, *center panel*), the neurons whose tuning curves overlap with the stimulus have become less responsive (in proportion to their amount of overlap), and so the population average shifts to the direction opposite to the adapted direction. Similar processes happen for all adaptation directions (e.g., $+15^\circ$ in the *right panel*). The result will thus act like an opponent code in some ways, since the effect is opposite the adaptation pattern and again there will be no net effect of adaptation to a static pattern. One difference is that this model does not require any specifically designated pairs of opponent pools and can thus use a single readout for all motion directions

process (Ball 2005; Ciroux 2005; Mather 1980). Instead, the apparent opponency of those dimensions may come from how the aftereffect is read out – using a population average, opposite directions of motions and opposite values along a hue dimension cancel out, which makes those dimensions be in opposition for perception and for aftereffects even though the actual mechanics of the neural model are multichannel.

Fatigue Versus Synaptic Inhibition

So far, adaptation has been described generically as a reduction in responsiveness, but we have not specified what makes the responsiveness decrease. Early neural explanations were in terms of “fatigue,” such as temporary depletion of some crucial resource inside a single cell. However, cortical cells do not appear to fatigue from repeated activation; they continue to respond vigorously to repeated electrical (non-synaptic) input

(Vidyasagar 1990). Instead, the observed reduced responsiveness appears to be synaptic in origin, primarily via inhibition from other neurons (Tollhurst and Thompson 1975; Webster 2012).

Moreover, an explanation in terms of synaptic changes seems more suitable for the McCollough Effect, in part because it does not require there to be large sets of neurons that are highly selective for both color and orientation (and every other similar feature conjunction for which a contingent aftereffect has been found). More importantly, the McCollough effect can last for days or even months, which would be difficult to reconcile with the time scale of recovery from any fatigue process, but is compatible with long-term storage of synaptic weights. Figure 6 shows results from multichannel TAE models of both types, either modeling reduced responsiveness directly (Series et al. 2009; Zhao et al. 2011) or via changes in lateral inhibition (Bednar and Miikkulainen 2000), and from the synaptic inhibition model applied to the McCollough effect (Ciroux 2005).

Visual Aftereffects, Models of, Fig. 6 Tilt aftereffect and McCollough effect in humans and models. (Left) Tilt aftereffect. Changes in perceived orientation are systematically related to the angle between the adapting and test stimuli, with a peak aftereffect (difference in perceived orientation) of several degrees for a 10–15° difference between the adapting and test orientations and an area of opposite (“indirect”) effect for the largest (45–90°) differences. Representative human data from one subject from Mitchell and Muir (1976) is shown with a black line; other subjects have similar shapes but with small differences in the peak orientations and location of the indirect effects. A multichannel model where responsiveness is reduced directly (Zhao et al. 2011; blue line) is a good match to the human direct effect, though it does not have any mechanism for generating indirect effects. A model based on

small increases to a large number of lateral inhibitory synapses (Bednar and Miikkulainen 2000; red line) also matches the direct effect but shows indirect effects as well due to homeostatic mechanisms limiting the total amount of synaptic efficacy (Bednar and Miikkulainen 2000). The synaptic model can also account for the McCollough effect (right) where the amount of perceived color difference (y axis) varies as a function of orientation (Ciroux 2005; human data from Ellis 1977). In this case, lateral interactions between color-selective neurons and orientation-selective neurons change as the test patterns are presented, gradually encoding the correlation between the color and orientation that reduces responsiveness to that pattern, causing a subsequent imbalance (and thus aftereffect) for the opposite-color test pattern

In this case, both approaches can fit the simple, direct tilt aftereffect and motion aftereffects. But the synaptic inhibition model can also explain contingent effects like the McCollough effect (via modification of lateral inhibitory interactions between orientation and color-selective neurons), as well as indirect tilt aftereffects (via whole-cell homeostatic plasticity mechanisms that lead to disinhibition of dissimilar neurons; Bednar and Miikkulainen 2000). Thus, the synaptic inhibition approach appears to be more widely applicable and also fits data not compatible with fatigue-type models (Webster 2012).

High-Level and Hierarchical Aftereffects

The aftereffects discussed so far have primarily been for relatively simple stimuli, for which specific feature-selective cells have been established clearly in animal and human visual systems. Aftereffects for many other types of patterns have also been demonstrated, but it is much more difficult to model these mechanistically given how little is known about the neural representation of such stimuli. For instance, a very wide variety of aftereffects have been reported for images of human faces, including aftereffects of identity, gender, emotion, and shape distortion, and there is as yet little agreement about appropriate models for these phenomena. For one thing, it is quite unclear even which level(s) of the visual system might be involved – assuming that neurons are adapting at lower levels, by the time the putatively face-selective neurons in higher areas are reached, the lower levels may well have adapted significantly. It has already been established that the presumably high-level task of detecting emotion can be dramatically affected by low-level adaptation to curved or tilted lines (Dickinson and Badcock 2013; Xu et al. 2006, 2008), indicating that many of the aftereffects thought to be “high-level” may instead be the combination of several low-level aftereffects. In the absence of hard data about the neural organization, there remains a lively debate between norm-based opponent coding and multichannel coding for explaining face aftereffects. A few

papers support multichannel encoding for putatively high-level features like gender (Storrs and Arnold 2012; Zhao et al. 2011), but a large community argues strongly for norm-based opponent coding for faces and face aftereffects (Leopold et al. 2001; Pond et al. 2013).

Functional Role of Aftereffects

In many cases, aftereffects are studied because of what they reveal about the organization and function of sensory systems, but one can also ask what function they themselves serve in visual processing. An influential theory due to Horace Barlow (1990) is that they reflect continuously ongoing neural processing to remove temporal correlations in the incoming sense data, leaving a temporally sparse representation that allows us to focus on novel items and changes. Many of the models mentioned above are based implicitly on this principle, and several of them show how aftereffects can arise from decorrelating processes identical to those that may drive the original emergence of feature selectivity during longer-term development (Ball 2005; Bednar and Miikkulainen 2000; Ciroux 2005). Note that each of these explanations relies crucially on having an “unaware” decoder (Series et al. 2009), one that is temporarily fooled by the changes in responsiveness, which may be important for drawing our attention to subtle stimulus changes. If the sensory bias due to adaptation persisted over time, presumably downstream neurons would themselves adapt, eventually erasing the effect. These processes can also be interpreted as a form of dynamic gain control (Mather et al. 2008), with the nervous system continuously adjusting its responsiveness to make the best use of its limited dynamic range. In any case, the ubiquity of aftereffects indicates that they are likely to be involved in functionally relevant aspects of sensory processing.

Visual Hallucinations and Migraine Auras

Jack D. Cowan

Department of Mathematics, University of Chicago, Gordon Center for Integrative Science, Chicago, IL, USA

Definition

Elementary visual hallucinations are geometric patterns that move with the eyes and are seen by almost all humans. They can be triggered in many ways. This article describes mathematical models

developed over the last 40 years of how such images are generated in the visual cortex, as a consequence of its circuitry and dynamics. The models use the Turing mechanism for pattern formation to generate cortical patterns of neural activity which are seen as hallucinations in the visual field. It provides an alternative to the standard way of studying vision using external stimuli, in using geometric patterns generated by internal changes in the stability of cortical activity. It provides a theory of how the four classes of patterns which are seen as hallucinations are formed in the visual cortex as a consequence of the way it is wired. It appears to be capable of also replicating the patterns seen in migraine auras.

Detailed Description

Elementary Visual Hallucinations

Elementary visual hallucinations are usually geometric patterns seen in the visual field that move with the eyes. They are seen under a variety of conditions, including sensory deprivation, flickering light, following the administration of anesthetics such as ketamine, and of course the use of psychedelic drugs such as peyote, marijuana, psilocybin, and LSD. They are also seen by some observers when falling asleep, or when waking up, or during meditation. There are also reports of hallucinations associated with schizophrenia, and under certain epileptic conditions. Interestingly many prehistoric cave paintings and rock carvings, dating back at least 30,000 years, appear to

contain examples of hallucinatory motifs, as do images found on pottery, dating back some 3000 years. Hominids have had a long history with hallucinations.

Klüver Form Constants

One of the first relatively modern studies was carried out by Purkinje early in the nineteenth century, who studied flicker phosphenes [see Purkinje (1918) and ► “Flicker-Induced Phosphenes” by Ermentrout & Billock in this volume]. However, the first modern study was carried out in the late 1920s by Heinrich Klüver. His observations were based on a personal study of the effects of peyote on perception and were summarized in Klüver (1966). Klüver organized the imagery he saw into four classes: (a) lattices, honeycombs, and chessboards, (b) cobwebs, (c) tunnels and funnels, and (c) spirals. He called these classes *form constants*. Figures 1 and 2 show examples of each form constant.

Note that based on such figures, elementary visual hallucinations can be further classified as comprising (I) *contoured* images, i.e., the form constants (a) and (b), and (II) *non-contoured* images such as stripes of blobs, i.e., the form constants (c) and (d).

Complex Hallucinations

There are, of course, much more complex hallucinations, many of which are also described in

Visual Hallucinations and Migraine Auras,

Fig. 1 Left panel: Class (a) Honeycomb hallucination generated by Marijuana (Redrawn from Clottes and Lewis-Williams 1998). Right panel: Class (b) Cobweb petroglyph (Redrawn from Patterson 1992)

Visual Hallucinations and Migraine Auras,

Fig. 2 Left panel: Classes (c) and (d) funnel and spiral hallucinations generated by LSD (Redrawn from Oster 1970)

Visual Hallucinations and Migraine Auras,
Fig. 3 Lattice tunnel hallucination (Reproduced from Siegel (1977), with permission from the artist Alan D. Iselin)

Klüver (1966). Figure 3, for example, shows an artist's impression of a hallucination which is *colored* and contains both lattice and tunnel elements.

In addition it seems that the first images to form during the experience are the elementary geometric forms, but later more complex forms appear. Figure 4 shows an impression of the progression of hallucinatory imagery from simple to complex.

Modeling the Neocortex

In order to develop an explanatory theory of how and where such imagery is generated in the brain, it is necessary to find a mathematical way to reduce the immense complexity of neural circuitry to something that is much simpler. This was the

starting point of the initial theory developed by Wilson and Cowan (1972, 1973), and used later by Ermentrout and Cowan (1979) to model hallucinations. In this theory the neocortex, specifically the visual cortex (V1), is modeled as a two-dimensional spatially homogeneous slab, with translation and rotation symmetry. It therefore has the symmetry of rigid body motions in the plane $\mathbb{R}^2$, i.e., the symmetry of the Euclidean group in the plane, $\mathbb{E}(2)$. It follows that the normal modes of vibration of V1 are *plane waves* of the form $\exp(i\mathbf{k} \cdot \mathbf{x})$, where $\mathbf{k}$ is the wave number or spatial frequency of the waves. This implies that if the form constants are generated in V1, then the type II non-contoured form constants are likely to be superpositions of such normal modes.

Pattern Formation in Neural Networks

This immediately poses the problem: how do stripes form in neural networks? This problem was solved by Ermentrout and Cowan by exploiting an analogy between neural networks with excitatory and inhibitory connections and Turing's theory of the formation of periodic patterns of stripes and spots in diffusion-coupled chemical reactions (Turing 1952). We can summarize the neural model in terms of the equation:

$$\frac{\partial}{\partial t} u(\mathbf{x}, t) = -\alpha u + \mu \int w_{\text{lat}}(|\mathbf{x} - \mathbf{x}'|) f[u(\mathbf{x}')] d\mathbf{x}' \quad (1)$$

where $u(\mathbf{x}, t)$ is neural activity, α is the decay constant, μ is the coupling strength parameter, w_{lat} is the effective Mexican Hat weighting

Visual Hallucinations and Migraine Auras, Fig. 4 Stages in the development of complex hallucinations (Redrawn from Clottes and Lewis-Williams 1998)

Visual Hallucinations and Migraine Auras, Fig. 5 The effective "Mexican Hat" weighting function

function shown in Fig. 5, and $f[u]$ is a nonlinear current function. [Note that because w_{lat} depends on the *magnitude* of the distance between $\mathbf{x}$ and $\mathbf{x}'$, it is invariant to rotations and is thus isotropic.]

Depending on the nature of the nonlinear function $f[u]$, Eq. 1 will generate periodic stripe or spot patterns. Thus, if f is dominated by the quadratic term in its Taylor series expansion, it will generate spots. Conversely if f is predominantly cubic, it will generate stripes. (See the article by Ermentrout & Billock in this volume for more details.) Note that periodic spot patterns are really superpositions of plane waves, i.e., stripe patterns (Fig. 6).

However, there is one other essential aspect to the theory. This concerns the fact that there exists a *topographic map* from the retina and visual field onto V1, the cortical retina. Away from the fovea this map from visual field coordinates (r, θ) to V1 coordinates (x, y) takes the form $x = \log r, y = \theta$, which is a form of the complex logarithm (Schwartz 1977; Cowan 1977). The remarkable fact is that under such a map, type II form

Visual Hallucinations and Migraine Auras, Fig. 6 Distribution of orientation preferences in Macaque V1 obtained via optical imaging. Different orientation preference patches are pseudo-colored (Redrawn from Blasdel 1992)

constants transform into superpositions of plane waves. This is the content of the Ermentrout-Cowan theory.

A Theory of Type I and II Form Constants

The extension of the Ermentrout-Cowan theory to account for the generation of type I form constants took 22 years. In large part this was due to the lack of experimental data on the distribution of iso-orientation preference patches in V1. It was not until Blasdel (1992) published the first optical imaging study of orientation tuning in V1 (see 6) that a solution began to emerge (Wiener 1994; Cowan 1997). Further studies combining cell staining techniques with optical imaging by Bosking et al. (1997) and Eysel (1999) led to a detailed theory (Bressloff et al. 2001).

This theory is based on the discoveries of Hubel and Wiesel (1959, 1962, 1974) that V1 is organized to detect visual features of retinal images, especially the orientation of contrast edges. Hence the organization into locally iso-orientation preference patches. This suggested to me circa 1993 that orientation preference should be treated as an internal V1 coordinate. This ultimately led to the Bressloff et al. model in which the V1 coordinate system becomes (x, y, ϕ) and the space $\mathbb{R}^2 \times \mathbb{S}$ where $\mathbb{S}$ is the circle. But the normal modes of vibration of the circle are sinusoidal, and in the case of orientation preference, they take the form $\cos 2\phi$, since orientation preference is a π -periodic variable. It immediately follows that the normal modes of vibration of V1 should be plane waves whose amplitude is modulated by $\cos 2\phi$, e.g., $\cos 2\phi \cos(\mathbf{k} \cdot \mathbf{x})$.

A Modified Retino-Cortical Map

However, there is now a new problem with the retino-cortical map. Inspection of the Bosking et al. paper indicated that there is an additional symmetry in V1 connectivity. Bosking et al. found that in the tree shrew, the horizontal connections between V1 Hubel-Wiesel hypercolumns connect corresponding iso-orientation patches of similar preference, and remarkably, the direction of such connections is *parallel* to this preference. Thus, if the orientation preference changes from ϕ to ϕ' , the direction must shift by $\phi - \phi'$. It turns out that this symmetry is used in computer vision (Zweck and Williams 2000, 2004) and is called a *shift-twist* symmetry. Remarkably it is used to preserve Euclidean symmetry in the plane when transforming to a discrete lattice, as is V1. This tells us that any model of V1 requires the rotation operator to have the shift-twist symmetry property. Thus, the retino-cortical map must express this symmetry. This is part of the Bressloff et al. model. Figure 7 shows the details of V1 circuitry.

Extending the Ermentrout-Cowan Model

Equation 1 is easily extended to incorporate such a connectivity pattern. The modified equation takes the form:

$$\frac{\partial}{\partial t} u(\mathbf{x}, \phi, t) = -\alpha u + (\mathbf{x}, \phi, t) + \mu \int_0^\pi \int_{\mathbb{R}^2} w(\mathbf{x}, \phi | \mathbf{x}', \phi') f[u(\mathbf{x}', \phi', \dots, t)] \frac{d\mathbf{x}' d\phi'}{\pi} \quad (2)$$

where $w(\mathbf{x}, \phi | \mathbf{x}', \phi')$ is the weight of connections between neurons at $\mathbf{x}$ tuned to the orientation ϕ , and neurons at $\mathbf{x}'$ tuned to ϕ' . We take the weighting function to decompose as

$$w(\mathbf{x}, \phi | \mathbf{x}', \phi') = w_{\text{loc}}(\phi - \phi') \delta(\mathbf{x} - \mathbf{x}') + \beta w_{\text{lat}}(\mathbf{x} - \mathbf{x}', \phi') \delta(\phi - \phi') \quad (3)$$

where $w_{\text{loc}}(-\phi) = w_{\text{loc}}(\phi)$, and β is the strength of the lateral coupling. The effects of the Dirac delta functions $\delta(\mathbf{x} - \mathbf{x}')$ and $\delta(\phi - \phi')$ acting inside the integrals are to *localize* the action of w_{loc} to $\mathbf{x}$ and w_{lat} to ϕ . The weighting function then contains a local part that is *isotropic* in ϕ (and inhibitory), and a lateral part that is *anisotropic* (and excitatory). In addition because lateral connections lie only along the direction of the orientation preference, we can see that

$$w_{\text{lat}}(\mathbf{x}, \phi) = w(R_{-\phi} \mathbf{x}) \quad (4)$$

where R_θ is the matrix operation that rotates the vector $\mathbf{x}$ by the angle θ . The effect of this rotation is that we can rewrite $w_{\text{lat}}(\mathbf{x} - \mathbf{x}', \phi)$ as $w_{\text{lat}}(R_{-\phi}(\mathbf{x} - \mathbf{x}'))$. The net effect of all this is that we can preserve Euclidean symmetry by redefining the rotation operation to express the above property of the weighting function, by defining the rotation operator to be not only $R_{-\phi} \mathbf{x}$; but also a label change of the orientation variable from ϕ to $\phi - \phi'$.

From the Euclidean Plane to the Euclidean Lattice

Figure 6 indicates that we need to model V1 as a lattice rather than a plane. This implies that V1 is almost *crystalline*. It follows that only the finite subgroups of $\mathbb{E}(2)$ are relevant in calculating the normal modes of vibration of V1. These subgroups are the *dihedral* groups $\mathbb{D}_n$, with $n = 2, 3, 4$, and 6 , and rotation angles that are multiples

Visual Hallucinations and Migraine Auras,

Fig. 7 Illustration of the isotropic local connections within a hypercolumn and the anisotropic lateral connections between hypercolumns. Connections between iso-orientation patches within any hypercolumn are inhibitory. Connections between iso-orientation patches in different hypercolumns are excitatory (Redrawn from Bressloff et al. 2001)

Visual Hallucinations and Migraine Auras,

Fig. 8 (Left panel) Contoured even axial planform on the square lattice. (Right panel) Contoured even axial planform on the hexagonal lattice

of π/n , corresponding to rectangular, rhombic, triangular, square, and hexagonal symmetry. Thus, the normal vibration modes of the lattice model of V1 are periodic lattice patterns with such symmetries. In what follows we refer to these patterns as *doubly periodic planforms*.

As a consequence, stable solutions of Eq. 2 comprise both even and odd contoured planforms of the forms, respectively, $u_E(x) = \cos 2\phi \cos(\mathbf{k} \cdot \mathbf{x})$ and $u_O(x) = \sin 2\phi \cos(\mathbf{k} \cdot \mathbf{x})$. Only the

even solution $u_E(\mathbf{x})$ generates contour completing even planforms, and it can be selected for by introducing a little spread in the lateral connectivity. In addition the non-contoured form $u(\mathbf{x}) = \cos(\mathbf{k} \cdot \mathbf{x})$ is also a stable solution. Thus, type I planforms are obtained from the even contour completing solutions, and type II planforms are obtained as in the original Ermentrout-Cowan theory. Figures 8 and 9 show the appearance of these solutions in V1 spatial coordinates, and

Visual Hallucinations and Migraine Auras,

Fig. 11 (Left panel) Non-contoured even axial planform on the square lattice. (Right panel) Non-contoured even axial planform on the hexagonal lattice

Figs. 10 and 11 show their appearance in the visual field.

It will be seen that these visual field planforms correspond precisely to type I and type II form

constants. Thus, the Bressloff et al. extended Ermentrout-Cowan model solves the problem of modeling the V1 origin of the Klüver form constants.

Further Extensions of the Model

Spatial Frequency Tuning

There are many other problems involving hallucinations. For example, optical image studies by Hübener et al. (1997) revealed that V1 is also organized into iso-spatial frequency preference patches, as shown in Fig. 12. This suggested to Bressloff and Cowan (2002) an extension of the model introduced in Bressloff et al. (2001) in which a second internal coordinate $\theta \propto \log p$, where p is the spatial frequency preference; and θ is a second angular component of the sphere S^2 . Thus, the space of V1 is now $\mathbb{R}^2 \times S^2$, and the two internal coordinates ϕ and θ are the angular coordinates of the sphere, with ϕ denoting the longitude; and θ the latitude. The poles of the sphere correspond to points where $p = p_{\min}$ and $p = p_{\max}$. It follows that the normal modes of the sphere S^2 now modulate the normal modes of the plane $\mathbb{R}^2$. But the normal modes of the sphere are *spherical harmonics*, the lowest order terms of which are products of terms such as $\cos 2\phi$ and $\cos 2\theta$. Thus, the requisite normal modes of $S^2 \times \mathbb{R}^2$ are of the form $\cos 2\phi \cos \theta \cos(\mathbf{k} \cdot \mathbf{x})$. The resulting Bressloff-Cowan spherical model can account successfully for the generation of both type

I and type II form constants, within a single unified framework, and therefore has some advantages over the earlier models. It has the further advantage that it may be possible to extend such a formulation to include hallucinatory images with color, depth, and motion.

Intrinsic Fluctuations

The work described earlier is all carried out within the framework established in the Wilson-Cowan equations. But these are *mean field* equations: they do not take account of the effects of correlations between differing neural sites, nor of the effects of intrinsic fluctuations of neural activity. It took just over 40 years to develop the required extensions. The resulting Stochastic Wilson-Cowan equations (Buice and Cowan 2007, 2009; Buice et al. 2010) can be used to analyze the effects of correlations and intrinsic fluctuations on the threshold for triggering hallucinations (Butler et al. 2012). The results indicate that in a general randomly connected network, fluctuation-induced hallucinations are ubiquitous. However, in a network connected with the V1 architecture described earlier, hallucinations only appear under mean field conditions, i.e., they only appear when parameters such as connection strengths change. This is consistent with data on the occurrence of hallucinations. Thus, it can be inferred that the long-range horizontal connections between V1 hypercolumns *stabilize* it against the effects of intrinsic noise. A similar result was found by Kaschube et al. (2010) in connection with the development of V1 iso-orientation preference patches.

Visual Hallucinations and Migraine Auras, Fig. 12 Relationship between spatial frequency and orientation maps. Gray regions denote low spatial frequency. Note that iso-orientation contours tend to cross the border of spatial frequency domains at right angles and that the *pinwheel centers* or singularities of orientation preference are often located at the centers of either low or high spatial frequency domains (*not highlighted*) (Redrawn from Hübener et al. 1997)

Migraine Auras

The final topic to be reviewed in this article concerns the *fortification* patterns, sometimes called *scintillating scotomas*, seen in migraine auras. Figure 13 shows two well-known examples of such scotomas. From these and similar sequences, it is possible to estimate the propagation velocity in V1 coordinates at about 1.5–3 mm/min, using the retino-cortical map. The scotomas look like

Visual Hallucinations and Migraine Auras, Fig. 13 *Left panel:* the development of a scintillating scotoma experienced while reading a book. The sequence starts with the upper-left panel and proceeds clockwise.

The entire episode lasts for about 20–30 min (Redrawn from Gowers 1904). *Right panel:* another scintillating scotoma observed during a migraine attack. Observed at times $t = 0, 3, 7$ and $t = 10$ min (Redrawn from Lashley 1941)

expanding circular waves in V1 coordinates (Grüsser 1995).

There have been a number of attempts to model the spread of such patterns, essentially by propagating a traveling wave of spreading depression over a model of V1, based largely on an early paper by Tuckwell and Miura (1978). Several papers along these lines have subsequently been published, e.g., Reggia and Montgomery (1996) and Dahlem and Müller (2004). The paper by Reggia and Montgomery (1996) tries to take into account V1 circuitry but lacks any representation of orientation preference and therefore fails to generate the appropriate local patterns seen by observers. It remains to develop a model including orientation preference in V1 circuitry that is capable of generating the patterns shown in Fig. 13.

Concluding Remarks

The topic of visual hallucinations covers many aspects which we have not touched on in this short article, which has been written in a somewhat parochial fashion. The reader is referred to a recent extensive review of the topic by Billock and Tsou (2012) for a less technical, but more extensive review.

Definition

A visual illusion is a discrepancy between perception and reality that stands out as an anomaly. This entry describes general approaches as well as specific models that have influenced our current understanding of the mechanisms leading to visual illusions. A “model” here means a set of computations aimed at making quantitative

predictions about the appearance of a visual stimulus. In some cases the computations are couched in terms of neural machinery, and in others the language of perceptual psychology. All the models discussed are generic in the sense that they aim to explain more than one illusion; however, none can be said to be truly universal. Importantly, the models are not necessarily mutually exclusive: many of them echo back to the “perceptual hypothesis” approach that is first described. Each model is accompanied by an example or two of the illusions it aims to explain. The entry does not however provide a comparative appraisal of the various models – this is beyond its scope – but references to critiques of many of the models are included. An important class of illusion that is not discussed is visual aftereffects, the perceptual distortions observed following adaptation (typically the result of prolonged viewing) to a related stimulus. The mechanisms of adaptation deserve an entry of their own, and the interested reader should consult the entry on aftereffects by James Bednar.

Detailed Description

What Are Visual Illusions?

Although there is no universally accepted definition of a visual illusion, most have defined it as a discrepancy between perception and reality (e.g., Gillam 1998; Gregory 2004; Wade 2005). This definition is arguably too broad, however, since it encompasses perceptual phenomena that in spite of being discrepant with reality do not make it into the pantheon of illusions that adorn the books, websites, and blogs that deal with the subject. A rainbow, for example, is perceived as a series of distinct bands of color (red, orange, yellow, green, etc.), yet physics informs us that its component wavelengths vary continuously not categorically across its width, a clear-cut instance of perception contradicting reality. Yet rainbows are not considered to be visual illusions. Dejan Todorovic (personal communication) suggests that we ascribe illusions to phenomena that are “exceptions to the rule,” the rule being that the dimension of interest is normally perceived

Visual Illusions, Models of, Fig. 1 The Ponzo illusion. The two horizontal lines are the same length

accurately. Thus, for example, the Ponzo and Müller-Lyer illusions in Figs. 1 and 2 are illusions because our perception of length, or rather relative length, is generally accurate, so the misperceptions stand out as anomalies. Color vision, on the other hand, due to its physiological limitations, is unable to tell us about a stimuli’s precise wavelength composition, so the rainbow does not strike us as an anomaly. In Todorovic’s words, for something to qualify as an illusion, it does not suffice that you are wrong; you must also be able to be right.

Perceptual Hypothesis Approach

One of the most influential theories of visual illusions is that we construct perceptual hypotheses about what we see based on our knowledge of the visual world acquired during evolution and/or development. Because the information provided by our senses is often limited or ambiguous, perceptual hypotheses impose structure to our visual experience, making up for the deficiencies of sense data. In general this results in more accurate perception, but under some circumstances, it leads to mistakes. The origins of the perceptual hypothesis approach lies in Helmholtz’s notion of “unconscious inference” (Helmholtz 1866/1962) and to some extent in the “organizational principles” of Gestalt psychologists (reviewed by Todorovic 2008). Its most notable proponent

Visual Illusions, Models of, Fig. 2 (a) the Müller-Lyer illusion. The vertical lines are the same length. (b) Gregory's explanation – see text for details

was the psychologist Richard Gregory (1966/1967, 2004), while the “empirical” theory of Purves and Lotto (2003) and the Bayesian approach to illusions (e.g., Weiss et al. 2002), both discussed below, are arguably its recent expressions.

The Ponzo illusion in Fig. 1 is a textbook example of the approach. The horizontal lines in the figure appear different in length even though they are physically the same. According to the perceptual hypothesis approach, we make the reasonable assumption that the upper line is further from view because the lines on either side appear to recede into the distance. However, because the retinal-image length of the horizontal lines is the same, we infer that the upper line must be physically longer, and that is how it is perceived.

Gregory's explanation for the Müller-Lyer illusion in Fig. 2 follows a similar logic (though see a different explanation in the section on “Channel Models”). Gregory suggests that the vertical line with the inward-pointing fins is interpreted as the outside corner of a building, whereas the line with outward-pointing fins is interpreted as the inside corner of a room. According to Gregory we assume we are closer to the outside corner than the inside one, so the line with inward-pointing fins, which casts the same-size image on our retina as the line with outward-pointing fins, by inference must be shorter, and that is how it is perceived.

Another illusion that lends itself readily to the perceptual hypothesis approach is the leaning tower illusion shown in Fig. 3 (Kingdom et al. 2007). The two photographs are identical, yet the tower on the right appears to lean more. The reason for the illusion is straightforward. If the

two towers rose physically at the same angle, their corresponding outlines would converge in the photograph due to perspective but be perceived as parallel because of the brain's inbuilt knowledge of perspective. However, in the pair of photographs in Fig. 3, the corresponding outlines do not converge but are parallel, so the visual system infers that the two towers must be diverging as they recede, and this is how they are perceived.

Empirical Model

An influential variant of the perceptual hypothesis approach is the “empirical” model best associated with Dale Purves and Beau Lotto (summarized in Purves and Lotto 2003) but which has many antecedents (e.g., Craven 1993). The model emphasizes the effect on perception of inbuilt knowledge of the statistical relationships in natural scenes acquired through accumulated experience, i.e., “empirically.” The empirical model has been applied to an impressive number of illusions (Purves and Lotto 2003). The general idea can be gleaned by considering how the model applies to the relationship between the orientation and perceived length of lines, as shown in Fig. 4. The figure shows that although perceived length is longer for vertical than horizontal lines – this is the well-known horizontal-vertical illusion shown in Fig. 5 – lines that are angled 20–30° off vertical are perceived to be the longest.

Craven (1993) measured the density of features along various orientations of lines in the 2D projection of images of natural scenes and found that feature density followed closely the pattern of perceived length shown in Fig. 4. Assuming feature density correlates with physical line length, Fig. 4 therefore embodies the relationships

Visual Illusions, Models of, Fig. 3 The leaning tower illusion. The two photographs of the Leaning Tower of Pisa are identical

Visual Illusions, Models of, Fig. 4 Perceived length of lines as a function of orientation (Based on Fig. 7.8 in Purves and Lotto (2003))

between the lengths of lines in the 3D image that project to the same length in the 2D image. More recently, Howe and Purves (2002) confirmed this physical relationship using a range finder that measured the actual length of lines in natural scenes as a function of their orientation and 2D projection lengths. Both groups of investigators conclude that variations in perceived length as a function of orientation reflect the variations in the

Visual Illusions, Models of, Fig. 5 The horizontal-vertical illusion. The two lines are the same length

physical lengths of 3D contours that give rise to equal-length contours in the 2D projection. In other words we perceive vertical lines as longer than horizontal lines because we have learned that lines that project vertically are on average longer than lines that project horizontally.

The physical variations in line length in the 2D projection are likely due in part to foreshortening, since the ground plane, upon which many objects lie, is tilted around the horizontal axis. However, foreshortening does not explain why perceived length is longest for lines 20–30° off vertical

Visual Illusions, Models of,

Fig. 6 Simultaneous brightness/lightness contrast. The two *gray* patches have the same luminance

(Craven 1993). The validity of the empirical approach however is not contingent on its ability to explain the physical basis of the image statistics that it assumes drives perception, only on showing a correlation between image statistics and perception.

The empirical approach has also been applied to a variety of brightness illusions (Purves and Lotto 2003). In the case of the simultaneous contrast illusion shown in Fig. 6, Purves and Lotto argue that patches on dark backgrounds are more likely to be lying in shadow compared to patches on bright backgrounds, and hence, two equal-in-luminance patches, one on a dark and one on a bright background, will likely have different reflectances, and that is how they are perceived (Purves and Lotto 2003 – for details see Williams et al. 1998). This explanation of simultaneous brightness contrast echoes back to Helmholtz’s explanation of simultaneous color contrast (Helmholtz 1866/1962; Kingdom 1997). Other brightness illusions such as the Craik-Cornsweet-O’Brien illusion (Fig. 10) and Mach bands (Fig. 12) are also explained in terms of image relations: in these cases it is suggested that the illusory percepts match physical illumination patterns that often arise because of the way non-diffuse illumination is reflected from the surfaces of three-dimensional objects. The relationship between the empirical and alternative models of brightness illusions is discussed further in Kingdom (2011).

Bayesian Models

Bayesian models of visual illusions also emphasize the importance of prior knowledge on

perception but incorporate it into a formal probabilistic framework. In a Bayesian model perception is based on the product of a “likelihood function” derived from sense data and a “prior probability” founded on previously acquired long-term knowledge. This product is referred to as the “posterior probability”; thus

$$\text{Posterior probability} = \text{likelihood function} \\ \times \text{prior probability}$$

To understand how this equation might underpin certain visual illusions, consider why objects appear to move more slowly at low contrast, as one observes when a car moves in fog (Stone and Thompson 1992). According to the Bayesian model applied to perceived speed (Weiss et al. 2002; Hürlimann et al. 2002), our perception of speed is influenced by an inbuilt assumption – the “prior” – that the speed of objects follows a Gaussian function centered on zero (i.e., stationary) with slow speeds being more likely than fast speeds, as shown in Fig. 7. Our primary source of information about an object’s speed however comes from sensory information, but because of internal noise, this information is uncertain. The speed derived from a sensory measurement can thus be modeled as a probability distribution centered on the actual speed of the object, with a spread determined by the amount of uncertainty. This is the likelihood function in Fig. 7. To arrive at a perceptual estimate of speed, the prior and likelihood functions are multiplied to form the “posterior” distribution, and perceived speed is given by the peak of the

Visual Illusions, Models of,

Fig. 7 Bayesian model of the “slow-speed-in-fog” illusion. (a) Model for a high-contrast moving stimulus. (b) Model for a low contrast moving stimulus. See text for details (Figure adapted from Fig. 1 in Hürmann et al. (2002))

posterior. This peak will tend to be lower than the physical speed because of the influence of the prior but importantly by an amount that depends on the spread, or uncertainty of the likelihood function. At high contrasts the likelihood function is sharp due to a high signal-to-noise ratio and hence will be little affected by the prior, but at low contrasts, the relatively lower signal-to-noise ratio results in a wider spread, and thus the peak of the posterior will shift to the left, resulting in a lower perceived speed. Other motion illusions have been wholly or in part explained by the influence of the prior assumption that motion is slow or zero (Weiss et al. 2002). A critique of the Bayesian approach as applied to the speed illusion and to cognitive neuroscience in general can be found in Bowers and Davis (2012).

Channel Models

A number of visual illusions have been explained in terms of the activities of visual neurons with

narrowband spatial-frequency and orientation tuning, such as the simple cells found in primate area V1, often termed “channels.” Critical to this class of model is that the channel outputs are subject to nonlinear interactions such as orientation inhibition (Blakemore et al. 1970; Motoyoshi and Kingdom 2003; Schwartz et al. 2009) and contrast normalization (Carandini and Heeger 2012). Consider the standard model of the tilt illusion, an illusion first reported by Gibson (1937). Figure 8 shows that a vertical grating embedded in a rightward-tilted surround grating appears slightly tilted to the left. The explanation of this illusion is that it is caused by inhibitory interactions between orientation-selective neurons responding to the different parts of the stimulus (Blakemore et al. 1970; Carpenter and Blakemore 1973; Georgeson 1973; Schwartz et al. 2009). In Fig. 8, the green and purple Gaussian-shaped plots represent the responses of orientation-selective neurons as a function of their

Visual Illusions, Models of, Fig. 8 Tilt illusion and orientation-inhibition model. When the vertical grating in (a) is embedded in a tilted surround (b), it appears tilted slightly in the opposite direction. The model on the right shows the responses of orientation-selective neurons as a function of their orientation preference to the center

(purple curve) and surround (green curve) gratings. Inhibition from the surround neurons is modeled as a the gray Gaussian distribution that when subtracted from the center, grating response causes it to become slightly skewed to the left, resulting in the shift in perceived orientation of the grating

preferred orientation. For the vertical grating in Fig. 8a, the response distribution is centered on the orientation of the stimulus. According to the model, perceived orientation is determined by the centroid or some other measure of central tendency of the distribution, resulting in veridical, i.e., “accurate,” perception of the grating’s orientation. However, when the grating is embedded in the rightward-tilted surround (Fig. 8b), the neurons responding to the surround (green plot) inhibit those responding to the center grating (subtract gray plot from unskewed purple plot), causing the latter’s response distribution to become slightly skewed to the left, together with its centroid.

The tilt illusion is sometimes referred to as “acute-angle expansion,” a term that characterizes other geometrical distortion illusions such as the Poggendorff, Zöllner, and Hering illusions (Westheimer 2008), the last of which is shown in

Fig. 9. Orientation inhibition is thus a possible explanation for these illusions as well.

In the above channel model, the perceived orientation of a pattern is given by the centroid (or some other measure of central tendency) of the distribution of neural responses across orientation preference. Centroids figure also in the explanation of geometrical illusions, but in this instance, it is the centroid of the distribution of pattern elements in space. Morgan et al. (1990) (see also Bulatov et al. 2011) have suggested that the computation of spatial centroids by vision serves to facilitate the fast and reliable estimation of an object’s location independently of its size and shape complexity and propose that the automatic extraction of centroids is the cause of the Müller-Lyer illusion (Fig. 2a). The idea is that the positions of the ends of the horizontal lines are perceptually shifted toward the centroids of the adjacent fins.

Visual Illusions, Models of, Fig. 9 The Hering illusion. The *red lines* are straight yet appear curved

A type of channel nonlinearity that has become the focus for explaining many brightness illusions is contrast normalization. Contrast normalization is the mechanism that tends to equalize the magnitudes of channel responses in a local region of space (Carandini and Heeger 2012). The best-known model of brightness illusions that incorporates contrast normalization is the ODOG (oriented difference-of-Gaussian) model of Blakeslee, McCourt, and colleagues (Blakeslee and McCourt 1999; Blakeslee et al. 2005). Closely related contrast normalization models have been proposed by Dakin and Bex (2003) and by Robinson et al. (2007). Convolving an image with an array of narrowband, linear filters tuned to different spatial frequencies and orientations, and then summing their outputs does not itself predict brightness illusions, because if the filters form a “complete” set, the output will be a more or less veridical copy of the original. In the Blakeslee and McCourt approach, two processes conspire to produce brightness errors. First, very low spatial frequencies are attenuated, and this accounts for a variety of contrast errors such as the well-known illusion of simultaneous contrast shown in Fig. 6 (see also Shapiro et al. 2008). The second is contrast normalization, which has the effect of boosting channels that produce relatively weak responses. Figure 10 shows the illusion known after its discoverer as White’s Effect (White 1979), and Fig. 11 the ODOG model of the illusion. In White’s Effect the gray bars lying on the dark phase of the grating appear lighter than those lying on the white phase, in spite of the fact that the bars on the black phase are surrounded more with white than black and the

Visual Illusions, Models of, Fig. 10 White’s Effect. The short *gray* bars are all of the same luminance, yet the bars on the *white* phase of the grating appear darker than those on the *dark* phase

bars on the white phase more with black than white. Thus, the direction of the illusion is the opposite to that of the simultaneous contrast display in Fig. 6 and is thus in its conventional form an example of “assimilation” (Kingdom 2014a). In the ODOG model, contrast normalization equates the root-mean-square (RMS) output across six orientation channels, each of which is a weighted linear sum of seven spatial-frequency

Visual Illusions, Models of, Fig. 11 ODOG model applied to White's Effect. (a) Filter profile, (b) filters of different spatial scales are summed at a given orientation, (c) filter gains as a function of center spatial frequency, (d) orientations of combined filters, (e) stimulus, (f) result of convolving each stimulus with d, (g) contrast normalization equates RMSs of filter outputs, (h) outputs are

summed across filter orientation, (i) the continuous line is the predicted brightness of a horizontal cross section of the stimulus, while circles are the results of point-wise brightness matching (Figure supplied by B. Blakeslee and M. McCourt, based on Fig. 1 in Blakeslee and McCourt (1999))

channels. The most responsive channels to White's stimulus are the relatively high spatial frequency, vertically oriented channels tuned to the inducer grating. Contrast normalization has the effect of enhancing the relative contribution of the horizontally oriented low-spatial-frequency channels that pool the luminances of the flanking bars with those of the test patches, causing the illusion.

In Dakin and Bex's (2003) model, contrast normalization equates channel responses across spatial frequency, not orientation, and they show that this provides a good explanation for the well-known Craik-Cornsweet-O'Brien illusion (see examples in Todorovic 1987), a version of which is shown in Fig. 12. The figure is created by attenuating the low spatial frequencies, a process termed high-pass filtering, of a two-tone image of Einstein. The result is that the luminances of the uniform regions on either side of the face are

identical yet appear very different in brightness. In Dakin and Bex's model, it is these physically attenuated low spatial frequencies that are enhanced perceptually by contrast normalization, causing the illusory brightness differences. Finally, contrast normalization has been suggested as the cause of the illusory bars known as Mach bands shown in Fig. 14 (Kingdom 2013).

For some illusions, the absence of channels at the high-spatial-frequency end of the spectrum is believed to be the cause. A close relative of the chromatic version of White's Effect is the ring pattern stimulus created by Monnier and Shevell (2003, 2004) shown in Fig. 13. A yellow-orange test ring (Fig. 13a) is embedded in either the lime (Fig. 13d) or purple (Fig. 13e) phases of a circular lime-purple grating, resulting in dramatic differences in hue. The hue of the test ring shifts toward that of the adjacent ring's chromaticity. Yet color

Visual Illusions, Models of, Fig. 12

A version of the Craik-Cornsweet-O'Brien illusion. The luminances on the “dark” on the *left side* and “bright” on the *right side* of the face are the same, as can be seen from the horizontal *rectangle* in the *top middle* that passes across the edge dividing the two sides

assimilation is insufficient to explain the magnitude of the illusion; if one surrounds each test ring with a uniform field of the same chromaticity as the corresponding adjacent ring in the ring pattern (Fig. 13b, c), the illusion is significantly reduced. Monnier and Shevell suggest that the assimilation from the adjacent rings is augmented by contrast effects from the nonadjacent rings. The purple and lime colors stimulate primarily the short-wavelength-sensitive “S” cones of the human color vision pathway, the purple eliciting positive and the lime negative S-cone responses. Monnier and Shevell propose that cortical neurons whose receptive fields have spatially antagonistic S-cone inputs (Conway 2001) cause the shifts in color, as illustrated in Fig. 13f, g. In Fig. 13f the response of the neuron is increased by + S-cone stimulation from the purple adjacent to the test ring and further by -S-cone stimulation from the nonadjacent lime ring, causing the test ring to shift dramatically toward purple. In Fig. 13g the combination produces instead a strong negative response, causing an opposite shift toward lime. If very fine-scale S-cone-sensitive neurons were present, they would tend to counteract the shifts produced

by the neurons whose receptive fields are shown in the figure with the result that there would be no illusion.

Edge-Bar Feature Models

A class of channel model that deserves a section of its own proposes that channel responses are interrogated by rules designed to produce a representation of the input image in terms of “edges” and “bars” (Watt and Morgan 1985; Morrone and Burr 1988; Kingdom and Moulden 1992; Wallis and Georgeson 2012). A good example of how these models apply to visual illusions is their application to one of the best-known brightness illusions, Mach Bands, which are the illusory bands seen at the foot and knee of a luminance trapezoid (Fig. 14a). Although edge-bar feature models differ in the details of the computations involved, the schematic in Fig. 14b–d captures the general idea. In the figure the trapezoid is processed by two channels, one with an “odd-symmetric” response profile (shown in purple) and the other with an “even-symmetric” response profile (shown in green). The “even” channel gives a strong response at the foot and knee of the trapezoid,

**Visual Illusions,
Models of,**

Fig. 13 Monnier and Shevell's (2004) ring patterns and proposed explanation for the illusory differences in hue. The ring shown in **a**, when embedded in the circular lime-purple gratings, **d** and **e** appears to be markedly different in hue depending on the phase of the grating it replaces (lime phase replaced on left, purple phase replaced on right). The effect is not simply due to assimilation from the neighboring bars, as shown in **b** and **c**, which show a reduced effect. **f** and **g** show the explanation based on a center-surround receptive field with antagonistic S-cone inputs – see text for details (The figure is based on Fig. 1 in Monnier and Shevell (2004), reproduced with permission of the authors)

whereas the “odd” channel’s response is zero at these points (the “odd” channel would produce a strong response at the location of a step edge, whereas the response of the even channel would be zero). The relatively greater “even” compared to “odd” response is interpreted as a “bar,” and that is what is perceived. A critical evaluation of edge-bar feature models as applied to brightness illusions can be found in Kingdom (2011).

Gestalt Models

The word Gestalt is German for “shape” or “form,” and in the context of vision is a byword for an organizational principle that groups parts of

stimuli into perceptual wholes, such that the whole is perceived to be greater than the sum of its parts (reviewed by Todorovic 2008). Gestalt grouping principles are believed to underpin a variety of visual phenomena, including illusions. One example is the model of lightness illusions proposed by Gilchrist and colleagues (Gilchrist et al. 1999; Gilchrist 2006) and in a significantly modified form by Bressan (2006), known generically as the “Gestalt anchoring model.” Lightness is the perceived reflectance or “shade of gray” of an object. The term anchoring refers to the process that converts relative lightness values into absolute ones, by associating a particular lightness

Visual Illusions, Models of, Fig. 14 Feature model of Mach bands. (a) a luminance trapezoid, whose profile is shown in (d), produces Mach bands – the illusory dark and bright bars on either side of the vertical midline. (b and c) show, respectively, the receptive-field profiles of an even-symmetric and an odd-symmetric filter. (e) shows the result of convolving the luminance profile in d with the two filters. Note that at the foot and knee of the trapezoid, there is a peak in even-symmetric (*green*) response but zero in the odd-symmetric (*purple*) response. Feature models interpret this relationship as indicating the presence of bars at this point. Note that due to the limitations of electronic reproduction, the pattern in a will not be rendered as accurately as in the laboratory display

(e.g., mid-gray, white) to a particular luminance (mean, maximum). In the Gestalt anchoring model, lightness perception results from the combined operation of multiple anchors within nested image frameworks, with the frameworks determined by Gestalt grouping principles such as “belongingness,” “common depth,” “common fate,” etc.

The principle of Gilchrist and colleagues’ model can be grasped by considering how it applies to the simultaneous contrast display in Fig. 6. The idea is that the stimulus is first divided into two local and one global framework. The global framework comprises the stimulus as a whole, whereas the local frameworks consist of the two surrounds and their respective test patches. Within each framework the anchor is the highest luminance, which is assigned white, and all other regions within the same framework are assigned grays according to their luminance ratio with respect to the anchor. Within the global framework, the white background of the stimulus as a whole is the highest luminance and therefore assigned white, and the two test patches are assigned identical lower lightnesses, since their luminance ratios with respect to the background are the same. However, for the two local frameworks, the patch lightness assignments are different. For the patch on the dark surround, the patch is the highest luminance and therefore assigned white. For the test patch on the light surround, the surround is the highest luminance and therefore assigned white, so the patch is assigned a value relative to it, i.e., mid-gray. The net patch lightnesses are the averages of the lightness values computed from the global framework (both patches equal and mid-gray) and the lightness values computed from the local frameworks (patch on dark surround white, patch on light surround mid-gray). The result is a higher lightness value for the patch on the dark compared to the light surround. Thus, although the global framework has an important influence on the lightnesses of the patches, it is the influence of the two local frameworks that causes the difference in patch lightness and hence the illusion. A critical evaluation of Gestalt anchoring models can be found in Kingdom (2011).

Layer Decomposition Approach

This approach, sometimes referred to as “intrinsic-image models,” posits that many visual illusions, but primarily those of brightness and lightness, are a consequence of the perceptual

decomposition of an image into “layers.” The main layers of interest in this regard are the reflectance (the physical correlate of perceived color and shade of gray), nonuniform illumination (e.g., shadows and shading), and transparency (a material that you can see through) layers. The layer decomposition approach has focused mainly on compelling demonstrations of the influence of nonuniform illumination and transparency on surface lightness, brightness, and color. Some proponents of the layer decomposition approach however go further and suggest that even in displays containing no obvious regions of nonuniform illumination or transparency, layer decomposition occurs with profound consequences for perception (Anderson 1997, 2001; Ekroll et al. 2004). This latter viewpoint has been termed by Kingdom (2011) the “strong” form of layer decomposition approach, to differentiate it from the “weak” form described above that deals only when visible regions of illumination/transparency are present.

The layer decomposition approach has its origin in the studies by Gilchrist and colleagues (Gilchrist et al. 1983; see also Gilchrist 1988), who observed that the magnitude of simultaneous lightness contrast was enhanced when two gray patches, normally seen as surrounded by materials

of different reflectance, were instead seen as lying in different illuminations. The luminance contrasts between the patches and their immediate surrounds were the same under both configurations, so Gilchrist argued that the enhancement of simultaneous contrast could not be due to the effects of local contrast but instead due to the presence of nonuniform illumination.

Computer-graphics technology has led to a plethora of demonstrations of a similar ilk, showing how depictions of transparency (e.g., Adelson 1993; Logvinenko et al. 2005), shading/shadows (Knill and Kersten 1991; Logvinenko 1999; Adelson 1993, 2000; Purves and Lotto 2003), and figure-ground relationships (Anderson and Winawer 2005) have a profound influence on brightness, lightness, and color. A good example is Beau Lotto’s figure of a cube made of colored squares with one side lying in shade (note however that Lotto does not hold to the layer decomposition approach – see Purves and Lotto 2003), shown in Fig. 15. The figure demonstrates that a depiction of nonuniform illumination causes two regions that are identical in color on the page (as revealed on the right of Fig. 15) to appear dramatically different in color. The difference in perceived color is in a direction toward that of the colors the blocks would need to be painted in

Visual Illusions, Models of, Fig. 15 The *middle* blocks on the *top* and *near* faces of the cube are identical in color on the page, as revealed on the *right* when the rest of the image is occluded (Figure courtesy of Beau Lotto)

order to produce the same image were the cube a real object and the shading real illumination (which raises the thorny philosophical question as to whether we should think of such figures as illusions at all!). The central claim of the layer decomposition approach is that the magnitude of the illusory differences in brightness and color in Fig. 15 is much greater than would be expected on the basis of simultaneous contrast (Fig. 6) and that therefore it is the process of layer decomposition, which aims to uncover the “true” lightnesses and colors of the squares, that causes the illusion (Adelson 1993; Anderson and Winawer 2005). However, other researchers have argued that brightness and color contrast play a much bigger role in these illusions than might be supposed and may even be the sole cause of the illusion (Todorovic 2006; Blakeslee and McCourt 2012; Kingdom 2011).

An example of the “strong” form of the layer decomposition approach is Anderson’s (1997,

2001) account of White’s Effect (Fig. 10). According to Anderson, the junctions formed by the ends of the letter bars with the two grating phases, known as “T” junctions, facilitate a process of perceptual scission, such that the gray stripes are treated as if part of a thin transparent veil overlaying the grating bars. According to this account, the gray stripes that are in phase with the dark phase of the grating are perceptually “split” into dark and light layers, with the dark layer simply part of the grating that runs continuously “underneath” and the light layer forming a thin veil “above.” On the other hand, the gray stripes on the white phase are split into a light background layer and a dark veil. Since the veil is the foreground layer, it dominates our perception and hence causes the illusion.

The role of layer decomposition is also revealed in a different type of color (chromatic) visual illusion that is shown in Fig. 16. Our visual system tends to attribute perceived color changes to the reflectance layer, and in the photograph of the tower block, this leads to the misperception that the orange color is paint, whereas in fact it is a sunset illumination on a gray surface. Other examples of such misperceptions are described in Kingdom (2008, 2014b).

Conclusion

A variety of models seek to explain visual illusions. Some models compete to explain the same illusion, as, for example, with White’s Effect (contrast normalization vs. layer decomposition) and the Müller-Lyer illusion (perceptual hypothesis vs. centroid feature vs. empirical). It is unlikely however that any one model/approach will ever explain all visual illusions. For example, it is hard to see how the leaning tower illusion will ever invite the same type of explanation as Mach bands, since the former involves relatively high-level physiological processes concerned with the computation of perspective, whereas the latter involves relatively low-level physiological processes concerned with the extraction of simple image features. What is certain is that visual

Visual Illusions, Models of, Fig. 16 In this photograph of a tower block, the orange color looks like paint, whereas it is in fact a sunset illumination on a gray surface (Reproduced with permission from B. Micklethwait)

illusions will continue to serve as critical tests for all computational models of visual processing.

Definition

Visual motion detection describes the process by which directional information about local image motion is extracted from the spatiotemporal excitation pattern of the photoreceptor array.

Detailed Description

Visual motion information is of utmost importance for all animals including man: motion information can signal the direction in which a prey, a predator, or a conspecific is moving. Furthermore, motion information can also signal the movement of the observer in space: during movement, the images of the environment will constantly shift across the observer's eyes, causing an optic flow that is specific for the various kinds of maneuvers executed. However, at the level of the photoreceptors, the direction in which the image is shifting locally is not explicitly represented. Rather, directional motion information needs to be extracted from the photoreceptor array by comparing the signals of neighboring photoreceptors over time. The exact nature of this process as implemented in the visual system of *Drosophila* is currently being studied in great detail, and much progress has recently been made in determining the neural circuits giving rise to directional motion information in this species.

The Reichardt Model of Elementary Motion Detection

Analyzing the turning tendency of the beetle *Chlorophanus viridis* walking on a spherical Y-maze, Hassenstein and Reichardt (1956) proposed a specific model of elementary motion detection that could account for their observations in a quantitative way. This algorithmic model for elementary motion detection consists of two subunits, which are mirror symmetrical to each other (Fig. 1; Reichardt 1961, 1987; Borst and Egelhaaf 1989). Each subunit reads the luminance values measured in two adjacent facets and multiplies them after one has been delayed by a temporal low-pass filter. The output values of both subunits are finally subtracted.

In contrast to a simple speedometer, for which the output increases linearly with image speed, the model predicts a speed optimum at which the response is maximal. This optimum speed is set by the time constant of the low-pass filter. Beyond the optimum speed, the response decreases again.

Visual Motion Detection in *Drosophila*, Fig. 1 The Reichardt model of elementary motion detection. The model consists of two mirror-symmetrical subunits sharing the same two input lines. Within each subunit, the signal from one input is processed by a temporal low-pass filter with time constant τ and subsequently multiplied (M) with the instantaneous signal derived from the neighboring input. The signals from both subunits are subtracted ($-$), giving rise to a directionally selective output

Furthermore, the optimum speed of periodic gratings is a linear function of the pattern wavelength. Thus, optimum speed divided by pattern wavelength remains constant. The dimension of this ratio is a temporal frequency. Thus, the Reichardt detector responds maximally to a certain number of spatial periods passing by a single photoreceptor, not to a certain image speed. In more general terms, the model predicts a highly counterintuitive dependence of the motion detection process on pattern properties, such as its spatial wavelength as well as its contrast. Following these seminal studies of Hassenstein and Reichardt, a number of experiments were performed showing the Reichardt detector to also underlie motion vision in house flies (Fermi and Reichardt 1963; Eckert 1973) and fruit flies (Goetz 1964, 1965). The optimum temporal frequency of both species was determined at ~ 1 Hz, which allows to infer the time constant of the filters involved. To assess

the sampling base of the elementary motion detector, sine-wave gratings of different wavelengths were used: for pattern wavelengths smaller than twice the sampling base, an inversion of the response, called “spatial aliasing,” is expected. Determining the wavelength at which the response becomes negative revealed a sampling base of 4.6° for *Drosophila* (Goetz 1964, 1965; Buchner 1976). This result matches exactly the inter-ommatidial angle of this fly species. Thus, nearest-neighbor interactions within the retina form the input to the Reichardt detector in the fruit fly.

General Architecture of the Fly Optic Lobe

The fly’s nervous system consists of two ganglia: the head and the thoracic ganglion (for an overview, see Strausfeld 1976). The largest parts of the head ganglion, the optic lobes, are devoted to the processing of information coming from the eyes. The optic lobes (Fig. 2) consist of four different neuropiles called the lamina, the medulla, the lobula, and the lobula plate. All these neuropiles exhibit the same columnar structure as the retina. The principle underlying this building plan is retinotopy, i.e., neighboring image points are

processed by neighboring facets in the eye and by neurons within neighboring columns in each of the neuropiles of the optic lobes.

The fly’s eye is composed of facets or ommatidia which are equipped with a set of eight photoreceptors, with six outer photoreceptors, R1–R6, surrounding the two central ones, R7 and R8. When activated by light, all fly photoreceptors become depolarized (for review, see Hardie and Raghu 2001). This depolarization is a fast process; thus, fly photoreceptors can follow sinusoidal luminance modulations up to 200–300 Hz depending on the fly species. The different photoreceptors in one ommatidium have different optical axes, but certain groups of photoreceptors within neighboring ommatidia have parallel optical axes. By connecting these groups of photoreceptors to the same postsynaptic target (Braitenberg 1967), the sensitivity of the system is increased without sacrificing acuity (Kirschfeld 1967). This principle is called “neural superposition.” Whereas the axons of photoreceptors R1–R6 stop in the lamina where they connect to large monopolar cells and amacrine cells, the axons of photoreceptors R7 and R8 run through the lamina and terminate in the specific layers of the medulla.

The lamina contains, in addition to wide-field amacrine cells, eight different cell types per column, which connect it to the medulla: five lamina

Visual Motion Detection in *Drosophila*,

Fig. 2 Schematic of the optic lobe of *Drosophila*.

The retina (red) built from repetitive facets is followed by four layers of neuropile, called lamina, medulla, lobula, and lobula plate. All these neuropile layers consist of retinotopically arranged columns. Within the lobula, the group of three HS cells is shown as reconstructed from stained tissue

monopolar cells, L1–L5, two centrifugal cells called C2 and C3, and the T1 cell (Meinertzhagen and O’Neil 1991). Photoreceptor synaptic transmission involves the release of histamine by R1–R6 (Hardie 1989). Histamine-gated chloride channels are expressed on the postsynaptic target cells of R1–R6 and mediate signal-inverting synaptic communication: a strong, transient hyperpolarization upon illumination onset of the eye, which is followed by a sustained component that disappears with increasing light intensity. When the light is switched off, a rebound depolarization is observed. The response of large monopolar cells L1 and L2 readily adapts to the mean luminance over several orders of magnitude while leaving its contrast sensitivity almost unchanged (Jaervilehto and Zettler 1971; Laughlin et al. 1987; Straka and Ammermüller 1991; Zheng et al. 2009).

Starting with the work of Cajal and Sanchez (1915), the columnar cell types of the medulla, lobula, and lobula plate have been identified and described on the basis of Golgi impregnations in the housefly (Strausfeld 1976) as well as in *Drosophila* (Fischbach and Dittrich 1989). Each medulla column houses more than 60 different cells. They can be roughly grouped into medulla intrinsic (“Mi”) and trans-medulla (“Tm”) neurons. The terminals of all neurons coming from the lamina ramify in specific layers of the medulla (Takemura et al. 2008, 2011). This layout suggests a splitting of photoreceptor signals into several parallel pathways that might subserve different functions such as the detection of form, polarization patterns, color, and motion processing. However, because of the small diameter of columnar neurons’ processes, until now, only a few electrophysiological recordings from identified neurons have been described (DeVoe 1980; Gilbert et al. 1991; Douglass and Strausfeld 1995, 1996). Therefore, the visual response properties of most columnar neurons in the medulla are unknown.

In the lobula plate, large neurons run perpendicular to the columns covering many hundreds or thousands of them with their dendrites. These are the lobula plate tangential cells, investigated in great detail in blowflies first by Hausen and Hengstenberg (Hausen 1984; Hengstenberg et al.

1982). A total of 60 different cells are found in the blowfly *Calliphora vicina*, all of which are motion sensitive. Some of these cells have also been described for *Drosophila melanogaster* (Fischbach and Dittrich 1989; Scott et al. 2002; Raghu et al. 2007; Joesch et al. 2008; Schnell et al. 2010). In both species, tangential cells can be grouped, according to their preferred axis of motion, into horizontal or vertical cells. Best studied are the groups of three HS (*horizontal system*) cells and, depending on the species, 6–10 VS (*vertical system*) cells. Interestingly, the same cells in different individuals turn out to be highly stereotyped with respect to the area covered by their dendrites within the lobula plate, but not with respect to the branching pattern (Cuntz et al. 2008). Using ablation experiments (Heisenberg et al. 1978; Geiger and Nässel 1981; Hausen and Wehrhahn 1983) as well as optogenetic activation (Haikala et al. 2013), lobula plate tangential cells are concluded to control the fly’s optomotor response.

Reichardt-Type Motion Computation in the Optic Lobe

The most significant response characteristic of the lobula plate tangential cells is their directional selectivity (Fig. 3): if a grating moves in one direction (the cell’s preferred direction), the cell depolarizes or fires a train of action potentials. When the grating moves in the opposite direction (the cell’s null direction), the cell hyperpolarizes or ceases to fire. In contrast, the photoreceptor signal is nondirectional, i.e., a single photoreceptor displays the same response regardless of whether the grating moves in one or the opposite direction. Thus, somehow a non-directional response at the photoreceptor level is transformed into a directional signal at the lobula plate tangential cell level. The Reichardt detector describes this transformation in amazing detail.

As mentioned above, one of the hallmarks of the Reichardt detector is its temporal frequency optimum: the larger the pattern wavelength, the higher the optimum speed. As already verified in

Visual Motion Detection in *Drosophila*, Fig. 3 Experimental setup (*left*) and recording of directionally selective responses of a VS-tangential cell (*right*). With the fly mounted underneath the objective of a fluorescence microscope, the neuron is whole-cell

patched at the soma while the fly views a grating moving up and down. During upward motion (“null direction”), the cell hyperpolarizes; during downward motion (“preferred direction”), it depolarizes and fires bursts of action potentials

the optomotor response, this property is also found in the visual responses of lobula plate tangential cells of fruit flies (Joesch et al. 2008). In contrast to the optomotor response, which is inherently slow, recordings in blowfly tangential cells also allowed for a comparison between the transients of cellular responses and the ones of the Reichardt detector. When the velocity of a grating is stepped from zero to a constant value, the Reichardt detector exhibits a transient ringing at the temporal frequency of the pattern motion before settling at the steady state (Borst and Bahde 1986). Such a transient ringing could indeed be observed in lobula plate tangential cells of the blowfly (Egelhaaf and Borst 1989). Furthermore, the amplitude of the ringing showed a characteristic time constant by which it decays to the steady state, which depended on the contrast of the moving pattern as well as on the pattern contrast before the onset of motion (Reisenman et al. 2003; Joesch et al. 2008). These findings led to an elaborated Reichardt detector with high-pass filters inserted in the crossarms, the time constant of which rapidly adapts (Borst et al. 2003). Given these modifications, the Reichardt model can

account for both the steady state and all transient response features of the lobula plate tangential cells in a detailed way. This statement applies not only to stimulus situations using velocity steps but also to Gaussian white-noise velocity profiles. When using such stimuli with different standard deviations, the response exhibited a velocity gain control, i.e., the response–velocity function was found to be steeper as the velocity fluctuations become smaller (Brenner et al. 2000). The Reichardt detector replicates this velocity gain control even when all its filter time constants are fixed (Borst et al. 2005). Finally, even though tangential cells spatially integrate the output signals of local motion detectors and, thus, should represent their summated output, the signals of individual motion detectors can be observed experimentally, when spatial integration is prevented either by presentation of grating motion through a slit or by local calcium measurements in fine dendritic branches. Both these techniques revealed local signals that have all the characteristics of local motion detectors of the Reichardt type (Egelhaaf et al. 1989; Single and Borst 1998; Haag et al. 2004).

Neural Implementation of the Reichardt Detector

Given the evidence that has been accumulated for Reichardt-like motion computation in the optic lobes of different fly species, the question naturally arises about its neural implementation: which neurons form the Reichardt detector? This problem has remained essentially unsolved for over half a century, with no or only little progress for many decades. Only recently, the advent of sophisticated neurogenetics methods in *Drosophila* allowed to elucidate the circuits for elementary motion detection. These techniques are all based on a two-component expression system where a so-called driver line defining the neurons where a certain effector gene is expressed is crossed with another line, the so-called reporter line, defining what gene is expressed (Brand and Perrimon 1993). Today, thousands of different driver lines are available, many of which reveal a high degree of specificity for expression in individual cell types of the optic lobe (Pfeiffer et al. 2008). Furthermore, many reporter lines have been developed allowing for blocking the synaptic output from neurons, activating neurons optogenetically as well as recording from neurons via genetically encoded calcium indicators (for review, see Borst 2009, Venken et al. 2011). Applying these techniques to the problem of local motion detection revealed (a) that luminance information from fly photoreceptors R1–R6 is split into two parallel motion circuits, specialized to detect the motion of luminance increments (ON channel) and decrements (OFF channel) separately, (b) that lamina neurons L1 and L2 are the prime input neurons to these circuits (L1- > ON channel, L2- > OFF channel), and (c) that T4 and T5 cells carry their output signals (ON- > T4, OFF- > T5) (Joesch et al. 2010, 2013; Eichner et al. 2011; Maisak et al. 2013).

Input Elements

As mentioned above, a single facet of the fly eye comprises two sets of photoreceptors: the

peripheral photoreceptors R1–R6 and the central R7 and R8. Early work on different mutants where either the central or the peripheral ones were defective indicated that motion vision relies primarily on R1–R6, and not on R7 and R8 (Heisenberg and Buchner 1977). The two most prominent target neurons of the peripheral photoreceptors R1–R6 are the large monopolar cells L1 and L2 of the lamina. This suggested that they conveyed the input signal to downstream motion detection circuits. First, evidence along these lines was provided by experiments where either behavioral responses (Rister et al. 2007) or electrophysiological recordings from lobula plate tangential cells were used as a read-out (Joesch et al. 2010): blocking both L1 and L2 led to a complete abolishment of the responses to gratings moving along any direction. The individual contribution of L1 and L2 was discovered in flies where either L1 or L2 was blocked, and, instead of gratings, edges of different contrast polarity were moved to probe the responses of lobula plate tangential cells (Joesch et al. 2010): while control flies responded to moving brightness increments (ON edges) and decrements (OFF edges) with about the same amplitude, flies with lamina neurons L1 blocked completely lost their response to moving ON edges, while their response to moving OFF edges was largely intact. The opposite was found for flies with lamina neuron L2 blocked: here, the response to moving ON edges was roughly as large as the one of control flies, whereas the response to moving OFF edges was severely reduced. These results were later confirmed in a study on behavioral responses of walking fruit flies (Clark et al. 2011). Together, these experiments suggest that the photoreceptor input from R1–R6 is split into parallel channels depending on the contrast polarity of the incoming signal: while lamina neurons L1 specifically transmit information about brightness increments to downstream motion circuits, lamina neurons L2 only allow information about brightness decrements to be passed onto further motion processing. Technically, such signal processing is referred to as “half-wave rectification.”

General Layout

The findings about the specific contribution of L1 and L2 to motion processing of brightness increments and decrements immediately suggest that in *Drosophila*, motion is detected in several separate circuits. Theoretically, there could be four such channels comprising all possible combinations between ON and OFF signals. However, apparent motion experiments in blowflies suggested that only two such channels exist, one for the interaction of ON signals and one for the interaction of OFF signals between neighboring image points (Riehle and Franceschini 1984). In these experiments, pairs of single photoreceptors were stimulated by light-ON and light-OFF flashes while recording from a motion-sensitive lobula plate neuron H1. Recordings from lobula plate tangential cells in *Drosophila* arrived at the same conclusion: only sequences of light pulses of the same contrast polarity (ON–ON and OFF–OFF) elicited significant responses, while light pulses of differing contrast polarity (ON–OFF and OFF–ON) failed to evoke any responses in lobula plate tangential cells (Eichner et al. 2011). Interestingly, using brightness steps instead of brightness pulses led to different results: while, again, ON–ON and OFF–OFF sequences along the preferred direction of the cell led to positive responses, ON–OFF and OFF–ON sequences elicited negative responses. While this so-called reverse phi phenomenon (Anstis and Rogers 1975) was usually taken as evidence for an interaction between ON and OFF stimuli, as in the original Reichardt detector, careful simulations of such circuits as well as experiments with flies with lamina neurons either L1 or L2 blocked revealed that such an inversion of the response is not necessarily indicative of an interaction between ON and OFF channels. Rather, it can be explained by the residual sustained response component of the lamina neurons taking into account the contribution of motion detectors at the edge of the stimulated areas in the visual field of the fly (Eichner et al. 2011; Joesch et al. 2013).

In summary, thus, the Reichardt detector is implemented in the visual system of the fly in two parallel circuits, one dealing with brightness

increments (ON channel) and the other one with brightness decrements (OFF channel) (Fig. 4). What could be the advantage of such a doubling of wiring expenditure? Without splitting and half-wave rectification, i.e., with just a single motion detector dealing with brightness going positive as well as negative, a multiplicative interaction – according to the sign rule of multiplication – would imply the output being positive when both input signals go positive as well as when both go negative. Such a processing rule seems hard to be implemented biophysically and indeed is unheard of in cellular neuroscience. If, however, the input signals are split according to their polarity with the negative ones being sign-inverted, subsequent circuits only deal with positive input signals reducing the problem of multiplication to a supralinear input–output characteristic as can easily be implemented by a voltage-gated ion channel. Interestingly, neurobiology is not the only area where such problems arise: analog electronics faced the same problem of multiplying positive as well as negative signals, and the solution in these days was what is called a “4-quadrant multiplier.” There, the input signals, prior to multiplication, were half-wave rectified, split into parallel ON and OFF channels carrying positive signals only, and subsequently multiplied in four separate multipliers. Their output signals were then added with the appropriate sign, with outputs from ON–ON and OFF–OFF multipliers having positive and the ones from ON–OFF and OFF–ON units having negative sign (Hassenstein and Reichardt 1956). This looks similar to what we find in the fly, except that the fly seems to discard two of the four units, reducing a true multiplication to a “2-quadrant multiplier.” In the context of motion detection, however, this does not have any functional consequences: since motion of rigid objects gives rise to spatial correlations between time-delayed signals at subsequent image pixels, an ON event at one location will always correlate with an ON event at a later point in time at a neighboring location, and the same holds true for OFF events. In other words, no correlations between ON and OFF events at neighboring locations will be indicative for physically moving objects. Consequently, a

Visual Motion Detection in *Drosophila*,

Fig. 4 Input organization and general layout of the Reichardt detector as implemented in the *Drosophila* nervous system. At the level of the lamina, the photoreceptor input is split and half-wave rectified into an ON (*L1*) and an OFF (*L2*) signal. Both signals feed into separate motion detection circuits

comparison of a 4- and a 2-quadrant detector reveals no significant differences in response to visual motion (Eichner et al. 2011).

Output Elements

Having identified lamina neurons *L1* and *L2* as the decisive input elements to two parallel motion

detector circuits allowed anatomy to guide the next steps. Indeed, two parallel processing streams had previously been postulated in the fly visual system, based on careful investigation of co-stratification of Golgi-stained columnar cells (Bausenwein et al. 1992), as well as cell-unspecific activity labeling using the deoxy-glucose method (Bausenwein and Fischbach 1992). These studies indicated that an *L1* pathway

should indirectly lead to columnar T4 cells and an L2-pathway to columnar T5 cells, with both T4 and T5 cells projecting to the lobula plate. Given that 4 different subtypes of T4 and T5 cells exist terminating in four different layers of the lobula plate (Fischbach and Dittrich 1989) and deoxy-glucose labeling indicated activity in one of the four layers according to the direction of the stimulus (Buchner et al. 1984), T4 and T5 cells were prime candidates for local elementary motion detectors and for representing the output signals of the ON and the OFF motion pathways, respectively. Their small size, however, prohibited electrophysiological recordings, and their visual response properties remained for long unknown. A recent study (Maisak et al. 2013) circumvented this problem by using driver lines specific for T4 and T5 cells and combining them with a high-sensitivity genetically encoded calcium indicator GCaMP5 (Akerbom et al. 2012). Using 2-photon

calcium imaging and stimulating the flies with grating motion in four cardinal directions (front to back, back to front, upward, downward), Maisak and colleagues recorded directionally selective activity from T4 and T5 cells in each one of the four lobula plate layers depending on the direction in which the grating was moving (Fig. 5). To assess the particular contribution of T4 and T5 cells to the signals observed in the above experiments, driver lines specific for T4 or T5 cells were used, respectively. Applying the same stimulus protocol and data evaluation as before, identical results were obtained for both the T4- and the T5-specific driver lines. Further experiments revealed similar response properties for T4 and T5 cells with respect to their orientation and velocity tuning (Maisak et al. 2013). If, however, instead of gratings, moving edges with either positive or negative contrast polarity were used as visual stimuli, T4 cells were found to

Visual Motion Detection in *Drosophila*, Fig. 5 T4 and T5 cells represent the elementary motion detector outputs. *Left:* confocal image of a driver line giving rise to expression in both T4 and T5 cells, shown as a horizontal cross section (Modified from Schnell et al. 2012). Neurons are marked in *green* (Kir2.1-EGFP labeled), revealing clear labeling (in *green*) in the medulla (T4 cell dendrites), in the lobula (T5 cell dendrites), and in four distinct layers of the lobula plate, representing the terminal arborizations of the four subpopulations of both T4 and T5 cells. The neuropile is stained in *red* by an antibody against the postsynaptic protein Dlg. The image within the *yellow square* is from a 2-photon microscope and contains the

area shown enlarged to the *right*. *Right:* 2-photon calcium imaging in the lobula plate reveals directionally selective signals. Following stimulation of the fly with grating motion along four cardinal directions (*front to back*, *back to front*, *upward*, and *downward*), activity is confined to mostly one of the four layers, depending on the direction in which the grating is moving. The outcome of all four stimulus conditions is combined into a single image by assigning a particular color to each pixel depending on the stimulus direction during which it responded most strongly. Depending on their preferred direction, T4 and T5 cells project into different layers of the lobula plate (Modified from Maisak et al. 2013)

strongly and selectively respond to moving ON edges, with little or no responses to moving OFF edges, while T5 cells selectively responded to moving OFF edges and mostly failed to respond to moving ON edges.

To investigate whether the specific response properties of T4 and T5 cells are visible in post-synaptic lobula plate cells and visually driven behavior, T4 and T5 cells were genetically blocked and flies subsequently tested. Blocking both T4 and T5 cells led to a complete loss of the motion response in lobula plate tangential cells (Schnell et al. 2012) and of the optomotor response of tethered walking flies (Bahl et al. 2013). Blocking T4 cells specifically led to selective loss of the responses to moving ON edges, in the electrical signal of tangential cells as well as in optomotor behavior. Conversely, blocking T5 cells led to a loss of the responses to moving OFF edges, again both in the electrical signal of tangential cells and in optomotor behavior (Maisak et al. 2013). In summary, the selective defects of T4 block flies for ON edges and of T5 block flies for OFF edges not only corroborate the above findings about the selective preference of T4 and T5 cells for different contrast polarities but also demonstrate that the signals of T4 and T5 cells are indeed the major, if not exclusive, inputs to downstream circuits and motion-driven behaviors.

Conclusion and Outlook

Local motion detection in *Drosophila* has long been shown to follow the predictions of the Reichardt detector. However, only the last few years have witnessed a major breakthrough in our understanding of its neural implementation. Making use of technology targeting genetically individual cell types and expressing proteins that either block synaptic transmission or signal neural activity led to the following picture (Fig. 6): starting with L1 and L2, the visual input is split into separate ON and OFF pathways, and motion along all four cardinal directions is computed separately within each pathway. The output of these eight different motion detectors is then

sorted such that ON (T4) and OFF (T5) motion detectors with the same directional tuning converge in the same layer of the lobula plate, jointly providing the input to downstream circuits and motion-driven behaviors.

As an immediate hypothesis derived from these findings, the dendrites of T4 and T5 cells could be the place where the signals from neighboring facets converge, giving rise to T4 and T5 cells direction selectivity. In the case of T4 cells, these cells have recently been described anatomically: using large-scale serial sectioning transmission electron microscopy and computer-aided reconstruction, Takemura and colleagues found two neurons, Mi1 and Tm3, to connect the output terminals of L1 neurons to the dendrites of T4 cells (Takemura et al. 2013). They furthermore observed an asymmetry of T4 cells' dendrites in their wiring to Tm3 and Mi1 going along with the lobula plate layer they project to, i.e., their direction selectivity. All this points in the direction that, indeed, processing as described by each subunit of the Reichardt detector is implemented in the fly's optic lobe. Future studies will have to determine which of the cells carries the delayed and which one carries the instantaneous signal, as well as characterize the nature of their interaction within the dendrites of T4 cells. In a similar way, the input signals to T5 cells, after their anatomical identification, will have to be investigated.

Another open question concerns the cellular nature of the subtraction stage in the Reichardt detector. Here, evidence exists in both blowflies and fruit flies that this subtraction is realized by a synaptic push–pull organization with local motion detectors of opposite preferred direction providing excitatory and inhibitory input onto the dendrites of lobula plate tangential cells (Borst and Egelhaaf 1990; Borst et al. 1995; Joesch et al. 2008). However, it is not known at present whether and how individual T4 and T5 cells could provide, at the same time, excitation to one and inhibition to the adjacent lobula plate layer.

Finally, the picture as shown in Fig. 6 will certainly be extended and elaborated by future studies, revealing more and more details of the motion detection circuitry. Indeed, recent studies

Visual Motion Detection in *Drosophila*, Fig. 6 Circuit diagram of the fly elementary motion detector (*left*) and some of the neurons involved (*right*). *Left*: visual input from photoreceptors R1–R6 is split into parallel pathways, L1 and L2, at the level of the lamina. Two neighboring columns are shown. The outputs from both L1 and L2 are half-wave rectified, such that downstream elements carry information about ON (L1 pathway) and OFF (L2 pathway) signals separately. After temporal low-pass filtering (LP), the signals from one column interact in a supralinear way with the instantaneous signals derived

from the other column. This interaction takes place, separately in both pathways, along all four cardinal directions. Directionally selective signals are carried via T4 and T5 cells to the four layers of the lobula plate where T4 and T5 cells with the same preferred direction converge again on the dendrites of the tangential cells (LPTCs) (From Maisak et al. 2013). *Right*: Golgi stains of L1 and L2 neurons, as well as of T4 and T5 cells. The signal from L1 terminals is conveyed to the T4 cell dendrites via two neurons, Mi1 and Tm3 (Takemura et al. 2013) (Modified after Fischbach and Dittrich 1989)

suggested an additional contribution of lamina neuron L3 to the OFF motion pathway (Silies et al. 2013), described the center-surround organization of the receptive fields of L2 neurons (Freifeld et al. 2013), and indicated more detailed response defects in motion-driven behavior following highly selective blockade of each of 12 lamina cell types (Tuthill et al. 2013). Thus, thanks to all the sophisticated tools available in *Drosophila*, the problem of the neural implementation of the Reichardt detector, after resisting for decades, will soon be understood in great detail.

objects, landing on environmental structures, overcoming narrow gaps in cluttered environments, locating a previously learned target based on environmental information, or tracking fast-moving targets. With regard to solving such tasks, insects often outperform man-made autonomous flying systems, especially if computational costs and energy efficiency are taken as benchmarks. To accomplish their extraordinary performance, several insect groups have been shown to actively shape the dynamics of the image flow on their eyes (“optic flow”) by the characteristic way they move when solving behavioral tasks. The neural processing of spatial information is greatly facilitated by such active vision strategies, for instance, by segregating the rotational from the translational optic flow component by way of a saccadic flight and gaze strategy. Flying insects acquire at least part of their strength as autonomous systems through active interactions with their environment, which lead to adaptive behavior in surroundings of a wide range of complexity. Model simulations and robotic implementations show that the smart biological mechanisms of motion computation and visually guided flight control might be helpful to find technical solutions for problems related to micro air vehicle navigation.

Visual Processing in Free Flight

Martin Egelhaaf
Neurobiology & CITEC, Bielefeld University,
Bielefeld, Germany

Definition

With their miniature brains, many insects are able to control highly aerobatic flight maneuvers and to solve spatial vision tasks, such as avoiding collisions with stationary obstacles and moving

Detailed Description

Flying animals, but also autonomous man-made flying systems, have to solve a number of fundamental tasks. Most basically, they need to control their attitude in three-dimensional space and to stabilize their intended flight course against disturbances. Moreover, they have to accomplish a number of tasks that rely on information about the spatial layout of their surroundings, for instance, when avoiding collisions with obstacles, negotiating narrow gaps in cluttered surroundings, or finding their way back to a previously learned location, such as a profitable food source or the often inconspicuous entrance of their home. In other situations, an animal may encounter other moving animals and either needs to avoid them in the case of a predator or may pursue one of

them, for instance, when it is searching for a prey or a mate. Visual information and its processing by the nervous system are crucial for solving such tasks in free flight. Self-motion through three-dimensional environments but also movements of other animals induce image displacements on the eyes and, thus, brightness changes on the two-dimensional array of photoreceptors, i.e., the input site of the visual system. All visual information required for solving any of the abovementioned fundamental tasks needs to be processed from these changes in the two-dimensional intensity distributions recorded at the photoreceptor level.

There are many ways how this may be accomplished. One particularly well-analyzed and functionally highly relevant possibility is based on the concept of optic flow that results from the image displacements on the eyes induced by self-motion and/or object motion. The optic flow depends on the dynamic characteristics of self-motion and of object motion, as well as on the three-dimensional structure of the environment. Therefore, the optic flow contains rich information on the way the animal moves around but also on the three-dimensional layout of the environment. Since the optic flow vectors defined by the retinal image displacements are not immediately available to the brain of the animal, representations of optic flow fields and of behaviorally relevant information that is contained in them need to be computed by the nervous system from the time-varying retinal brightness changes as sensed by the lattice of photoreceptors. This processing is done in a sequence of steps before the extracted information can be used by the animal to solve visual tasks. Optic flow as a source of information is particularly relevant for fast-flying animals, including many insects, but also some bird species: (1) Given that during flight animals do not have direct contact to the ground, they rely much more on visual information and, in particular, optic flow information for controlling their attitude in space than when walking. (2) Since flight takes place in three dimensions, the resulting optic flow may be much more complex than during locomotion on the ground: Movements are characterized by six degrees of freedom, three rotational

and three translational components reflected in the corresponding optic flow components. (3) Especially during the often highly aerobatic flight maneuvers of many insects, the optic flow fields may have complex dynamical properties that are related to both the characteristic dynamics of flight behavior but also the animal's spatial relation to the objects and surfaces in its surroundings. (4) In contrast to most current technical flying systems, which frequently employ systems such as infrared sensors and the global positioning system for obtaining positional, distance, and range information, animals apparently do not have access to such systems and have to rely on optic flow information for solving spatial tasks during flight.

Geometry of the Retinal Motion Patterns Induced by Self-Motion and Object Motion

The optic flow generated by self-motion in a stationary environment has characteristic geometrical properties which depend on the movement vector as well as on the three-dimensional layout of the environment. A point on a surface in the environment is given by the position vector $\mathbf{P} = (X, Y, Z)^T$ relative to the eye-centered coordinate system (T represents the transpose of the vector). When the eye moves in the environment, $\mathbf{P}$ moves in time t along the corresponding three-dimensional path $\mathbf{P}(t) = (X(t), Y(t), Z(t))^T$ in the eye-centered coordinate system (Fig. 1). Its velocity is given by the time derivative of this path

$$\begin{aligned} \mathbf{V}(t) &= d\mathbf{P}(t)/dt \\ &= (dX(t)/dt, dY(t)/dt, dZ(t)/dt)^T \quad (1) \end{aligned}$$

If we assume that the eye moves in a stationary and rigid environment, all points of an object share the same three rotational and translational motion vectors in the eye-centered coordinate system. Then the time-dependent velocity vector $\mathbf{V}(t)$ can be expressed in terms of the

Visual Processing in Free Flight, Fig. 1 Relationship between self-motion and the motion of the retinal image of an object in the environment. The optic flow generated by self-motion in a stationary environment has characteristic geometrical properties which depend on the movement vector as well as on the three-dimensional layout of the environment. A point on an object in the environment is given by the position vector $\mathbf{P}$ in the eye-centered

coordinate system. When the eye moves in the environment according to a translation vector $\mathbf{T}(t) = (T_x(t), T_y(t), T_z(t))^T$ and a rotation vector $\mathbf{\Omega}(t) = (\Omega_x(t), \Omega_y(t), \Omega_z(t))^T$, $\mathbf{P}$ moves with velocity $\mathbf{V}(t)$ in the eye-centered coordinate system. This results in a time-dependent displacement of the image of the object on the retina, i.e., the image plane of the eye at a velocity $\mathbf{v}(t)$. f represents the distance between the eye's nodal point and the image plane

instantaneous translation $\mathbf{T}(t) = (T_x(t), T_y(t), T_z(t))^T$ and rotation $\mathbf{\Omega}(t) = (\Omega_x(t), \Omega_y(t), \Omega_z(t))^T$ vector, respectively (Longuet-Higgins and Prazdny 1980; Heeger and Jepson 1992)

$$\mathbf{V}(t) = d\mathbf{P}(t)/dt = (dX/dt, dY/dt, dZ/dt)^T = (\mathbf{\Omega} \times \mathbf{X} + \mathbf{T}) \quad (2)$$

Any motion of the eye in the environment results in a time-dependent displacement of the brightness values on the retina, i.e., the image plane of the eye. The retinal image sequence can be described as a function $\mathbf{L}(x, y, t)$, with the brightness value $\mathbf{L}$ at image position (x, y) and time t . The velocities of the image points are then given in the most general form by

$$\mathbf{v} = (dx(t)/dt, dy(t)/dt)^T \quad (3)$$

The optic flow vectors are geometrically related to the movement vector of the eye and the location of the surface points in the environment as well as their spatial relationship. The

surface points in the environment $\mathbf{P}(X, Y, Z)^T$ project to the image point $\mathbf{L}(x, y)^T$ according to

$$x = fY/Z \text{ and } y = fX/Z \quad (4)$$

f represents the distance between the eye's nodal point and the image plane. Substituting Eqs. 2 and 4 into Eq. 3 leads to the following expression for the image velocity after some conversion

$$\mathbf{v} = (dx(t)/dt, dy(t)/dt)^T = 1/Z(x, y)\mathbf{M1}(x, y)\mathbf{T} + \mathbf{M2}(x, y)\mathbf{\Omega} \quad (5)$$

Z is the distance of each image point on the eye to its corresponding surface point in the environment. $\mathbf{M1}$ and $\mathbf{M2}$ are matrix expressions that only depend on the image position and the distance of the image plane f from the nodal point of the eye (for details see Heeger and Jepson 1992). The field of velocity vectors $\mathbf{v}$ at all points in the image plane of the eye represents the optic flow field.

The most important conclusion from a functional point of view that can be drawn from Eq. 5

is that the velocity vectors consist of two terms: The first term is referred to as the translational component of the flow field; it depends on translation velocity T of the eye in three dimensions and on the depth structure of the environment, i.e., the distance to environmental objects. The second term reflects the rotational component; it only depends on rotation velocity of the eye Ω in the environment, but not on the distance to objects (Fig. 2). Since the distance term $1/Z$ and translation velocity are multiplied, both a larger distance and a slower translation velocity result in a slower image velocity. This implies that the spatial information in the translational optic flow component is ambiguous. Accordingly, spatial information can be extracted from the optic flow field only in relative terms unless the translation velocity is known (Longuet-Higgins and Prazdny 1980).

Additional complexities may arise in natural environments where, for instance, brightness often varies over time, i.e., when clouds occlude the sun. In the latter case, not every change in brightness at the level of photoreceptors is generated by motion. Moreover, not every motion yields a change in brightness values: If the eye passes an un-textured surface, the optic flow within the object area cannot be recovered without

additional information. Even at object edges, where the brightness of the background differs from that of the object, the direction of object motion can only be recovered if more information is available, for example, at object corners. As a consequence of this aperture problem and the other aspects sketched above, it is not possible to derive the geometrically correct optic flow vectors from the displacements of individual image points without additional information about the physical structure of the environment and the way the observer moves (Heeger and Jepson 1992; Borst and Egelhaaf 1993).

The degrees of freedom of stimulus space and, thus, the abovementioned ambiguities are constrained by physics. Environmental structures tend to change only on a rough spatial scale; as a consequence, the probability is large that neighboring image points are similar (“spatial smoothness constraint”). Moreover, animals cannot change their direction of motion instantaneously but are limited by the physics of force production through muscles as well as by friction and inertia, depending much on the shape and mass of the body (“temporal smoothness constraint”). However, input dynamics might also be shaped – beyond constraints imposed by physics –

Rotation

Translation

Visual Processing in Free Flight, Fig. 2 Schematic illustration of the consequences of rotational (left diagram) or translational self-motion (right diagram) for the resulting optic flow. Superimposed images were either generated by rotating a camera around its vertical axis or by translating it forward. Rotational self-motion leads to image movements (green arrows) of the same velocity

(indicated by arrow length) irrespective of the distance of environmental objects from the observer. In contrast, the optic flow elicited by translational self-motion (red arrows) depends on the distance between objects from the observer. Hence, translational optic flow contains information about the spatial layout of the environment

by active flight and gaze strategies. All these features may help to reduce the ambiguities when it comes to optic flow estimation and to facilitate processing of information about the animal's self-motion and the three-dimensional layout of the environment.

If the environment is not entirely stationary but contains moving objects, the motion patterns generated on the eyes are constrained not only by the animal's self-motion but also by the velocity and trajectory of the moving objects. Assume for convenience that the eye is stationary and a single object of half-size l approaches the eye on a straight collision course at a constant velocity v . Further assume $x > 0$ being the object's position relative to the eye (i.e., $x = 0$ corresponds to the eye's position) and $t < 0$ representing the time before an impending collision (i.e., $t = 0$ corresponds to the time of expected collision). Consequently, the object's velocity, v , is < 0 when the object is approaching. The object's position during a collision course is then given by $x(t) = vt$, and, by trigonometry, its retinal angular size θ can be determined by $\theta(t) = 2 \tan^{-1}[l/(vt)]$. Hence, the temporal dynamics of the retinal image is fully determined by its size-to-speed ratio, $l/|v|$. For a given $l/|v|$, the retinal size of an object on a constant collision course initially increases only slowly, i.e., the retinal expansion velocity is small, but then its size appears to explode increasingly with decreasing distance to the eye, with the velocity vectors always pointing away from the center of the approaching object (Fig. 3a, b). Exactly the same time course of θ is obtained for all pairs of l and v as long as the ratio $l/|v|$ is kept constant (Fotowat and Gabbiani 2011).

Constraints Imposed on the Visual Input During Free Flight

The dynamical properties of retinal image displacements that are generated during free flight are largely shaped by the animal's flight style and how its gaze direction is controlled. Flight and gaze strategies have been analyzed in detail for some insect species, especially flies and flying hymenopterans, such as bees, but also for some

bird species. They are characterized by sequences of rapid saccade-like turns of body and head interspersed with translational flight phases during which the gaze direction is kept largely constant (Fig. 4) (Land 1999; Zeil et al. 2008; Egelhaaf et al. 2012; Kress et al. 2015; Ros and Biewener 2017). Saccadic gaze shifts have a rather uniform time course; in insects they are shorter than 50 ms. Angular velocities of up to several thousand degrees can occur during saccades. Since roll movements of the body, which are performed for steering purposes during saccades and also during sideways translations, are compensated by counter-directed head movements, the animal's gaze direction is virtually kept constant during intersaccades, with details depending on the particular species under consideration. Hence, turns that are inevitable to reach a behavioral goal are minimized in duration and separated from translational flight phases.

This peculiar time structure facilitates the processing of spatial information because only the optic flow component induced by translations contains information about the relative distance of environmental surfaces and objects from the animal: Surfaces and objects nearby pass quickly, while those far-off appear virtually stationary (Fig. 2). A saccadic flight and gaze strategy thus constrains the spatiotemporal properties of the optic flow on the eyes in such a way that visual information processing in spatial tasks as diverse as collision avoidance, flight speed control in cluttered environments is facilitated (Egelhaaf et al. 2012). Moreover, in many behavioral situations, e.g., when negotiating narrow gaps in cluttered environments or learning the spatial layout of the surroundings of a goal, such as an inconspicuous nest hole in the case of foraging bumblebees, the insects may use additional active vision strategies and perform characteristic flight maneuvers with pronounced lateral translational components that appear to be specifically tuned to gather spatial information by systematically scrutinizing the outside world. In other behavioral situations, the motion patterns being perceived are not only generated as a consequence of self-motion of the animal. If another object, such as a predator, a prey, or a potential mate, moves in the

Visual Processing in Free Flight, Fig. 3 Escape from an impending collision with a moving object. (a) Variables characterizing looming stimuli generated by an approaching object viewed by an insect eye. A solid object (red disk) with half-size, l , approaches the eye at a constant speed, v . $t = 0$ is the time of expected collision and $t < 0$ before collision. Consequently, the object's velocity, v , is < 0 when the object is approaching and $|v|$, the absolute value of v . $\theta(t)$ is the angular size of the object as seen by the eye. The time course of θ is fully determined by the size-to-speed ratio, $l/|v|$. (b) Kinematics of looming stimuli. Both the angular size, $\theta(t)$, (blue curve), and speed, $\dot{\theta}(t)$,

(green curve) of an approaching object grow nonlinearly with time. (c) If a locust is approached by a moving object, it initiates an escape response. The time to collision at takeoff is linearly related to the size-to-speed ratio of the looming stimulus. (d) The response to a looming stimulus of an identified wide-field neuron in the locust third visual neuropile increases with increasing retinal size of the object and reaches a peak before the impending collision. The relation between the peak time and the size-to-speed ratio of the looming stimulus is close to linear. (Adapted from Fotowat and Gabbiani 2011)

animal's visual field, the visual input is shaped by both the animal's self-motion and the direction and velocity of the moving object relative to the animal.

Processing of Visual Motion Information

The velocity vectors characterizing the retinal optic flow patterns during both self-motion and object motion are not directly available to the visual system. Rather the two-dimensional array of photoreceptors has access to only the two-dimensional pattern of time-dependent brightness changes. The first stage of visual motion processing is generally thought to be the computation

of local motion information from the brightness changes at neighboring locations in the retinal lattice (Fig. 5a). The second stage of visual motion processing is the interpretation of this neural representation of optic flow in terms of the direction and velocity of the animal's self-motion and of object motion, on the one hand, but also in terms of the properties and distances of stationary surfaces in the three-dimensional world, on the other hand. Although much is known about how these visual processing steps may be accomplished by flying animals, there are still many open questions.

Biological motion detection mechanisms get their input from a retinotopic array of discrete sampling points given in insects by the

Visual Processing in Free Flight, Fig. 4 Saccadic flight and gaze strategy of free-flying blowflies. (a) Sample flight trajectory of a blowfly flying in a flight arena with textured walls. Downward view of a flight trajectory (dotted line), with head position and orientation shown every 50 ms (time color coded: start, red; finish, green). (b) Orientation of the fly's longitudinal body axis (solid red line) and flight direction (dotted blue line) in the external coordinate

system. (c) Angular velocity of the body orientation of the fly (solid red line) and of the flight trajectory (dotted blue line). The fly changed its gaze and heading direction through a series of short and fast body turns. Flight direction and body axis orientation frequently deviate. The body axis already points in the new flight direction while the fly continues moving on its previous course. (Adapted from van Hateren et al. 2005)

ommatidial lattice. The number of ommatidia (facets) ranges from only some tens to up to 10,000 (Land 1997). Thus, compared with technical imaging systems, the number of sampling points and the spatial resolution of insect eyes is very low. Nonetheless, this low spatial resolution appears not to be detrimental given the fact that many insects are well able to perform highly aerobic flight maneuvers and to solve sophisticated spatial tasks that are based on optic flow information (see below).

The most prominent computational mechanism proposed as the basis of local visual motion processing in flying insects, but also birds and even humans, is the correlation-type motion detector (Reichardt 1961; Borst and Egelhaaf 1989, 1993; Egelhaaf and Borst 1993). This mechanism was originally proposed on the basis of behavioral experiments with beetles but has been characterized in detail by electrophysiological analyses in the visual system of flies. In its simplest form, a local motion detector is composed of two mirror-symmetrical subunits

(Fig. 5b). In each subunit, the signals of adjacent light-sensitive cells receiving spatially and temporally filtered brightness signals from neighboring points in visual space are multiplied after one of them has been delayed. The final detector response is obtained by subtracting the outputs of two such subunits with opposite preferred directions, thereby considerably enhancing the direction selectivity of the motion detection circuit. Each motion detector responds with a positive signal to motion in a given direction, i.e., either horizontally or vertically, and with a negative signal to motion in the respective opposite direction. Various elaborations of this basic motion detection scheme have been proposed to account for the responses of insect motion-sensitive neurons under a wide range of stimulus conditions, including even natural optic flow as experienced under free-flight conditions (Egelhaaf et al. 2012; Borst 2018). During the last years, much progress has been made by combining the sophisticated repertoire of genetic and molecular approaches in *Drosophila* with

Visual Processing in Free Flight, Fig. 5 Major processing steps of visual motion computation in insects. (a) Schematic of the visual motion pathway. Images of the moving environment are projected on the array of photoreceptors. The input is spatially and temporally filtered before signals originating from neighboring points in the visual space interact with each other. These interactions lead to local motion measurements. The outputs of many retinotopically organized local movement detectors are spatially pooled by wide-field neurons. Their output signals are involved in the control of various motion-driven behavioral components. (b) Organization of a local movement detector in its simplest form. The movement detector

receives spatially and temporally filtered signals from neighboring points in space. The detector consists of two mirror-symmetrical subunits. In each subunit, one of the inputs is temporally delayed (τ), before it interacts nonlinearly with the undelayed signal of the other detector input. A multiplication-like interaction (M) is the lowest-order nonlinearity that is sufficient to account for many aspects of motion detection. The subunit outputs contribute to the response of the wide-field neurons with opposite polarity, i.e., the two signals are subtracted. (c) Example of a wide-field neuron in the third visual neuropile of the blowfly. The cell was filled with a fluorescent dye, before it was visualized under a fluorescence microscope

electrophysiological and imaging techniques to identify the different components of the neural circuits underlying the correlation motion detection scheme. From a computational point of view, an especially relevant result is the separation of the input circuits of the movement detector into an ON and OFF pathway processing separately brightness increments and decrements (Mauss et al. 2017; Yang and Clandinin 2018; Strother et al. 2017).

The local motion measurements provided by correlation-type movement detectors do not provide a veridical representation of the optic flow vectors. Even if at each retinal location the corresponding pair of local movement detectors most sensitive to horizontal and vertical motion,

respectively, is combined to a local motion vector, its direction and amplitude may considerably deviate from the geometrically correct velocity vector. Several aspects of biological motion detectors are of particular functional relevance (Egelhaaf and Borst 1993; Egelhaaf et al. 2014): (1) *Velocity dependence* – Local motion detectors do not operate like odometers, even if the time or spatial average of their responses is taken into account. Their mean response increases with increasing velocity, reaches a maximum, and then decreases again and, thus, does not reflect pattern velocity unambiguously. The response characteristics of biological motion detection systems are even more complex, since their velocity maximum depends on the textural properties of

Visual Processing in Free Flight, Fig. 6 (a) Time-averaged velocity responses of a wide-field neuron in the blowfly third visual neuropile to grating patterns of different spatial wavelengths (red curve: 6.6°; blue curve: 21.5°; green curve: 36.3°) moving horizontally in the neuron's preferred direction. Velocity-response curves strongly depend on the pattern properties; their optima are shifted to higher velocities with increasing spatial wavelength of the pattern. (Data from Eckert 1980) (b) Consequences of dendritic integration on the representation of visual motion: Schematic of a directionally selective wide-field neuron with two branches of its dendrite, the axon and the axon terminal. The wide-field neuron receives

retinotopically organized input from many local motion detectors (vertical lines terminating with "synapses" red dots (excitatory synapses) and blue dots (inhibitory synapses) on the dendrite). As a consequence of this input, the cell is excited by motion in its preferred direction and inhibited by motion in the null direction. Even when the velocity of motion is constant, the activity of the local movement detectors is modulated depending on the texture of the surround within its receptive fields. Traces on the right indicate the time-dependent signals of three local input elements of the wide-field neuron. By dendritic pooling of many local elements, this pattern dependence in the time course of the responses is reduced (left trace)

the moving stimulus pattern (Fig. 6a). The pattern dependence of velocity tuning is reduced if the stimulus pattern consists of a broad range of spatial frequencies, as is characteristic of natural scenes. Despite these ambiguities, free-flying flies and bees appear to regulate their translation velocity to keep the retinal velocities in that part of the operating range of the motion detection system in which its response increases monotonically with retinal velocity (see below). (2) *Time course of local motion responses* – The responses of the local movement detectors do not represent the local pattern velocity unambiguously because they prominently depend on the local pattern properties that are perceived by their input elements. Since these response modulations of neighboring movement detectors are phase shifted with respect to each other, spatial pooling of many of these, especially along the direction of motion, mainly reduces – depending on the spatial extent of pooling – those pattern-dependent

response modulations that originate from the high spatial frequencies of the stimulus pattern (Fig. 6b). (3) *Motion adaptation* – Motion-sensitive neurons adapt to the prevailing stimulus conditions, at the expense of veridical speed coding, thereby increasing their sensitivity to velocity changes, such as those that can be induced during translation by nearby objects. This feature has been interpreted as an adaptation to facilitate spatial vision (Liang et al. 2008; Li et al. 2017; Kurtz 2012).

Not in all instances is optic flow processing in flying insects based on directionally selective movement detectors described by the correlation model. In a specialized circuit tuning wide-field neurons in locusts and, probably, also in the fruit fly *Drosophila*, to looming stimuli as evoked by an approaching object, the retinotopic excitatory inputs of these neurons have been concluded not to rely on the direction of motion. Rather their responses depend on the brightness changes

evoked by retinal image displacements and the increase of these changes when the object comes closer to the eye. With increasing retinal speed, as the object comes closer, the latency of the inputs decreases, favoring synchronization of inputs sequentially activated throughout the looming sequence making the neuron maximally sensitive to an impending collision (Fotowat and Gabbiani 2011; Dewell and Gabbiani 2018). Whereas this computationally parsimonious principle serves a special circuit for detecting an object on a collision course, correlation-type movement detectors are thought to be employed by flying insects in solving a broad variety of motion-dependent orientation tasks, such as course control, object-induced orientation, collision avoidance with stationary surfaces in the environment, or even landmark-based local navigation, which require robust motion information and need to combine local movement detectors in versatile, task-dependent arrangements.

Optic flow elicited by self-motion is specified by global rather than merely local features depending on flight direction and on whether the animal basically translates or rotates but also on the three-dimensional layout of the environment (see above). This implies that mechanisms extracting optic flow information from the retinal input need to combine local motion measurements from large areas of the visual field. Accordingly, local motion information has been shown to be spatially pooled on the extended dendrites of wide-field neurons in the insect visual system or, more specifically, the third visual neuropile, the lobula complex (Figs. 5c and 6b). The way how this may be accomplished is likely to depend on the task that is solved by the respective system. In flies, where the mechanisms of task-dependent spatial pooling of local motion information have been analyzed in detail, a population of some tens of individually identifiable neurons and their synaptic interactions has been characterized in the third visual neuropile. Due to their spatial input organization and specific synaptic interactions, these neurons respond preferentially to retinal motion patterns that may be relevant in different behavioral contexts (Hausen 1984; Krapp 2000; Borst et al. 2010;

Borst 2014; Egelhaaf et al. 2012; Egelhaaf 2006; Egelhaaf and Kern 2002).

Local motion information from different parts of the visual field needs to also be combined in an appropriate way if, for instance, an approaching object is to be detected. To a large extent, this situation is characterized by looming stimulation, i.e., by moving motion vectors pointing away from the edges of the object, while its retinal size increases as a consequence of the approach (see above). Again in locusts and, most recently, flies where flight behavior induced by approaching objects has been analyzed, wide-field neurons have been characterized in detail in the third visual neuropile and at later processing stages that appear to process this kind of retinal image expansion and to be tuned to such looming stimuli (Fotowat and Gabbiani 2011; Dewell and Gabbiani 2018).

Optic Flow as Information Source for Flight Control

Flying animals have to solve a variety of behavioral tasks that all rely on different aspects of visual motion information. These can be grouped into three different functional classes depending on what the motion information is used for: (1) to determine the attitude and self-motion of the animal in three-dimensional space, (2) to obtain spatial information on the environment from the translational optic flow component, and (3) to gain information about other moving objects. Some particularly well-analyzed behaviors will be addressed in the following – whenever possible, with respect to the neural mechanisms involved.

Estimation of Self-Motion in the Context of Attitude Control and Course Stabilization

Wide-field neurons that are thought to sense self-motion of the animal and to play a role in determining self-motion for course control have been characterized in a number of insect species. The underlying neural mechanisms have been investigated in flies in great detail. The preferred directions of the local motion detectors that synapse onto a given wide-field neuron appear to coincide to some extent with the directions of the velocity

vectors characterizing the optic flow induced during particular types of self-motion. The specificity of wide-field neurons for certain types of optic flow is much enhanced by synaptic interactions with other wide-field neurons in the ipsilateral and/or contralateral half of the visual system. As a consequence, individual wide-field neurons strongly respond to certain types of self-motion, such as rotations around the vertical axis of the visual system or different axes in the horizontal plane (Hausen 1984; Krapp 2000; Taylor and Krapp 2008; Borst 2014).

These wide-field neurons are commonly thought to mediate compensatory optomotor turning movements of the head and/or of the entire body. These behavioral responses have commonly been analyzed in flight simulators in tethered flight rather than in free flight. The fly generates turning movements of the head and the body to follow the moving pattern. These are usually interpreted to reflexively stabilize gaze direction and/or the flight course by minimizing the retinal velocities, for instance, resulting from external and/or internal disturbances (Taylor and Krapp 2008; Hengstenberg 1993; Hardcastle and Krapp 2016). As a general feature, compensatory optomotor turning responses are relatively slow: During maintained motion stimulation, they build up over several hundreds of milliseconds. Hence, optomotor feedback is likely to play a role on a slow timescale, for instance, to compensate for steady asymmetries at the level of the sensory input (e.g., internal gain differences) or the motor output (e.g., worn-out wings). Hence, the motion-sensitive wide-field neurons in the third visual neuropile may play a role in compensating unintended slow deviations of the animal from its flight course, after their output signals are considerably temporally low-pass filtered. So far, it is not clear where in the nervous system and by what mechanisms this filtering is accomplished. Since in free cruising flight gaze stabilization during intersaccadic intervals with their duration of only some ten milliseconds appears to be very fast, it is unlikely to be controlled by optomotor feedback (Egelhaaf et al. 2012). In addition to the body, the head of many analyzed insects, such as flies and bees, performs compensatory optomotor

movements on a fast timescale. In free flight, compensatory head movements are most prominent during roll rotations of the body, as are generated during banked saccadic turns and during sideways translations. Although head muscles receive synaptic input from motion-sensitive wide-field neurons, the functional role of visual motion for mediating compensatory head movements under free-flight conditions is still not entirely clear given the extremely rapid timescale at which gaze direction is stabilized during saccadic flight maneuvers, the response latencies, and the relatively slow time course of visually mediated head responses (Rosner et al. 2009).

Optic Flow as a Source of Spatial Information About the Environment

To facilitate the evaluation of spatial information from the optic flow, a range of flying animals such as many insects but also some bird species are thought to largely separate the translational and rotational optic flow components not by computational means but by behavioral strategies (see above). During cruising flight, the time that flies and bees keep their gaze direction largely constant amounts to more than 80% of the overall flight time. Rotations are comparatively short and very rapid (Fig. 4). This saccadic flight and gaze strategy has been interpreted as a way to facilitate gathering environmental cues and, in particular, spatial information from the retinal image flow during intersaccadic transitory self-motion (see above). In addition, insects can further adapt their flight and gaze strategies in an apparently targeted way to the environmental situation depending on the particular behavioral task the animal needs to solve.

Three distance-dependent features of the optic flow are of special functional significance. (1) Since the retinal velocity of an object scales with distance, an object nearby will lead to larger intersaccadic movement detector responses than a more distant one. A cluttered spatial scenery is segmented in this way, without much computational effort, into nearby and distant objects (Schwegmann et al. 2014; Egelhaaf et al. 2014). The representation of nearby objects is further enhanced by motion adaptation at the level of local motion detectors (Li et al. 2017) (Fig. 7).

Visual Processing in Free Flight, Fig. 7 Encoding of spatial information by two-dimensional arrays of local movement detectors during translatory locomotion in a natural environment. All images represent one instant of time during a longer translation sequence. (a) Original input image (after a nonlinear Naka-Rushton-like transformation of brightness values). (b) Contrast-weighted nearness map: The nearness (i.e., the inverse distance of the observer to any point in the 3D environment) is multiplied by the local contrast at the corresponding image location, resulting in the largest contrast-weighted nearness values at the edges of nearby objects (color code in arbitrary units). (c) Activity profile of the array of movement detectors while the observer moves through a natural environment

staggered in depth (see inset). The activity profile is given by the local motion energy, i.e., the absolute values of horizontally and vertically aligned local movement detectors; model simulations based on an elaborated version of the correlation-type movement detector (color code arbitrary units). The activity profile reflects the contrast-weighted nearness structure of the three-dimensional environment. (d) Activity profile of the array of movement detectors at one instant of translatory motion after the depth structure of the forest environment has been equalized by projecting it on the surface of a sphere (see inset). Model simulation as in c. The activity profile now reflects all contours in the environment irrespective of their distance. (Data from Schwegmann et al. 2014)

(2) The retinal velocity range and, thus, the spatial range that can be encoded by the motion vision system are limited by, among other factors, neuronal noise resulting from the biophysical mechanisms of neural computation (Laughlin 1994; Warzecha et al. 2013). Under spatially constrained conditions where flies fly at translational velocities of only slightly more than 0.5 m/s, the spatial range within which significant distance-dependent intersaccadic responses are evoked in motion-sensitive neurons amounts to approximately 2 m. Since a given retinal velocity is determined in a reciprocal way by the distance of objects and velocity of self-motion, respectively, the spatial range that is represented by such neurons increases with increasing translational velocity. Hence, the behaviorally relevant spatial range scales with intersaccadic flight velocity. From an ecological point of view, this scaling of the behaviorally relevant depth range is economical: A fast-moving animal should, for instance, initiate a turn leading to an avoidance maneuver at an earlier point of time and at a greater distance from an obstacle than when moving slowly (Egelhaaf et al. 2012). (3) The optic flow is largest orthogonal to the direction of translation. Therefore, the corresponding part of the visual system is most sensitive to distance changes. Hence, an animal should move sideways, if spatial information needs to be gathered in the frontal visual field. Indeed, prominent sideways flight components can be observed in many behavioral situations when the animal appears to scrutinize the spatial layout of its environment (see below).

Spatial information derived from optic flow and represented in the visual motion pathway is used by free-flying insects in a variety of behavioral contexts. Five of these will be sketched here:

- **Control of Translatory Flight in Spatially Constrained Environments** All flying insects investigated appear to regulate their overall translation velocity depending on spatial layout of the environment and, in particular, on the width of the corridor available for flight. Insects decelerate if the width of a flight tunnel used for experimental analysis becomes

narrower or if the flight path is obstructed by objects. Flight speed is thought to be controlled by optic flow generated during translational flight. Flies, bees, and moths were concluded to keep the optic flow on their eyes at a “preset” total level by adjusting their flight speed. Accordingly, they decelerate when the translational optic flow increases, for instance, while passing a narrow segment of a flight corridor (Srinivasan 2011; Srinivasan and Zhang 2004; Lecoeur et al. 2019; Linander et al. 2016; Egelhaaf et al. 2012; Kern et al. 2012). Not all parts of the visual field equally contribute to the input of the flight velocity controller: The most prominent role can be attributed to the intersaccadic optic flow generated in eye regions looking in front of the insect (Fig. 8). In these regions of the visual field, the intersaccadic retinal velocities are kept in a range of the motion vision system where the responses of the motion vision system still increase monotonically with increasing velocity and decrease with decreasing velocity (Egelhaaf et al. 2012).

- **Avoiding Collisions with Environmental Surfaces by Controlling Saccadic Turns**

In many situations, objects or other structures in the environment may interfere as obstacles with the animal’s trajectory that need to be avoided. Thus, collision avoidance represents a basic but highly relevant spatial task. Optic flow information is the most relevant cue involved in mediating collision avoidance with environmental structures in fast-flying insects. This has been shown in detail both for tethered and free-flying flies. The evasive responses in free flight are based on the characteristic saccadic turns of insects, whereas those observed in tethered flight are much slower and, thus, only reflect to some extent what is going on under free-flight conditions. There is consensus between studies that the largely translational optic flow during intersaccadic intervals is relevant in controlling the direction and amplitude of saccades that lead to collision avoidance. However, it is still inconclusive which optic flow parameters may be most relevant. Nevertheless, all

Visual Processing in Free Flight, Fig. 8 (a) Control of translational velocity in free-flying blowflies. Boxplot of the translational velocity in flight tunnels of different widths, in a flight arena with two obstacles and in a cubic flight arena (sketched below data). Translation velocity strongly depends on the geometry of the flight arena. (b) Boxplot of the retinal image velocities within intersaccadic intervals experienced in the fronto-ventral

visual field (see sketches above data diagram) in the different flight arenas. In this area of the visual field, the intersaccadic retinal velocities are kept roughly constant by regulating the translation velocity according to clearance with respect to environmental structures. The upper and lower margins of the boxes in a and b indicate the 75th and 25th percentiles, and the whiskers the data range. (Data from Kern et al. 2012)

proposed mechanisms of evasive saccadic responses rely on some sort of asymmetry in the optic flow pattern in front of the two eyes. The asymmetry may be due to the location of the expansion focus of the flow pattern in front of one eye or to a difference between the overall optic flows in the visual fields of the two eyes (Bertrand et al. 2015; Lecoœur et al. 2019; Serres and Ruffier 2017). Not all parts of the visual field appear to be involved in saccade control in the context of collision avoidance. In blowflies, for instance, the optic flow in the lateral visual field does not play a role in determining the direction of evasive saccades. This feature is likely to be related to the flight style of blowflies (Egelhaaf et al. 2012). During intersaccades they predominantly fly forward with some sideways components immediately after saccades that shift the pole of expansion of the flow field slightly toward frontolateral locations (Kern et al. 2012). In contrast, *Drosophila*, hoverflies, but also bees are able to hover to some extent and to fly sideways. Here, also lateral and even rear parts of the eye

may be involved in eliciting evasive saccades in the context of collision avoidance (Muijres et al. 2014; Braun et al. 2012; Geurten et al. 2012).

- **Active Visual Strategies to Facilitate Spatial Vision when Negotiating Narrow Gaps** In cluttered natural environments, insects are not only confronted with having to avoid obstacles. They often have to fly through small gaps without damaging their wings. This requires estimating whether a gap is wide enough to get through unharmed. The identification of gaps and the assessment of their passability are therefore elementary aspects of aerial navigation. The optic flow generated on the eyes during self-motion is the most plausible source of the spatial information necessary to accomplish this task. It has been shown for bumblebees that they follow a dedicated active vision strategy to generate the optic flow that provides the relevant information necessary to estimate the width of a gap and to control an adequate flight maneuver that ensures injury-free passage through it. When

approaching a gap, bumblebees decelerate at some distance to the gap, if the gap appears to have a critical width. The bees then gradually trade off their longitudinal velocity to lateral velocity and approach the gap with increasing lateral displacements. When the gap becomes more difficult to pass, the bees spent an increasing amount of time moving laterally in front of the gap. During these repeated lateral maneuvers, which generate pronounced translatory optic flow in the frontal visual field, the bees are probably assessing gap geometry and passability by using motion parallax (Ravi et al. 2019). By this active flight strategy, the bees are able to assess whether the gap is sufficiently wide to be able to fly through head first in normal flight orientation or whether they have to pass in an oblique or sideways orientation (Fig. 9). The bees thus seem to “know” their own body size along their different axes, since they behave in this peculiar way even if they had no prior experience with the respective environment. Hence, bumblebees adapt their flight and gaze

strategies to the situational context in such a way that they are able to cope with a multitude of unexpected spatial challenges in cluttered environments in order to fulfil their overarching foraging tasks.

- Active Visual Strategies During Local Navigation Based on Landmark Information** Whereas all flying insects should be able to avoid collisions with obstacles and to overcome narrow gaps, local navigation is a special ability of hymenopteran insects, such as bees, some wasps, and ants, which care for their brood and, thus, have to return to their nest after foraging (Zeil 2012; Zeil et al. 2009; Collett and Collett 2002; Collett et al. 2013). Nevertheless, basic elements of local navigation could also be found in *Drosophila* where the underlying neural circuits can be unraveled to some extent thanks to the broad repertoire of genetic approaches (Kim and Dickinson 2017; Green et al. 2017; Dewar et al. 2017; Turner-Evans and Jayaraman 2016). Visual landmarks represent crucial spatial cues and are employed to localize a goal, especially if it is barely

Visual Processing in Free Flight, Fig. 9 Bumblebees are able to relate the width of a gap to their body-size when they want to pass it. The experimental analysis was done in a flight tunnel with an obstructing wall containing a gap of variable width. Bumblebees decelerated at some distance to the wall and approached the gap with increasing lateral displacements depending on the width of the gap. During

the lateral maneuvers, the bees are likely assessing whether the gap was sufficiently wide to be able to fly through headfirst in normal flight orientation or whether it had to pass in an oblique orientation. Because the wingspan is larger than the body length, the bumblebees flew almost sideways through narrow gaps. (Data from Ravi and Egelhaaf)

visible. Information about the landmark constellation around the goal is memorized by bees during elaborate learning flights: The animals perform characteristic flight sequences while facing the area around the goal. During these learning flights, the animal somehow gathers relevant information about the landmark constellation that is subsequently used to relocate the goal when returning to it after an excursion. Although a variety of visual cues, such as contrast, texture, and color, are relevant in defining landmarks and are employed to find the goal, it is getting increasingly clear that also the spatial layout of the landmark constellation plays an important role and that landmarks that are defined by motion cues alone can be used by bees to locate the goal (Egelhaaf et al. 2012; Dittmar et al. 2011). Although the mechanisms by which the landmark constellation is learned and the memorized information is eventually used to locate the goal are not fully understood so far, it is clear that optic flow information actively generated during the bees' typical learning and searching flights is essential for the acquisition of a spatial memory of the goal environment (Zeil 2012; Zeil et al. 2009). Moreover, in the vicinity of landmarks, the animals adjust their flight movements depending on the specific textural landmark properties (see above). Since landmarks close to the goal are, for geometrical reasons, most suitable to pinpoint the goal location because the retinal locations of close landmarks are displaced more than distant ones during translational movements, the relevance of environmental objects to serve as landmarks for local navigation in the vicinity of the goal is weighed without any additional computational effort – just as a consequence of the geometrical properties of the optic flow induced during intersaccadic translational movements (see above). Processing of behaviorally relevant visual information is, thus, facilitated by the characteristic active gaze strategy employed during free flight (Egelhaaf et al. 2012).

The neuronal mechanisms underlying visual landmark navigation are not yet

known, although a variety of models for navigation on different spatial ranges have been proposed on the basis of behavioral experiments, anatomical evidence, functional imaging, and electrophysiological recordings (Philippides et al. 2016; Hoinville and Wehner 2018; Stone et al. 2017; Webb and Wystrach 2016; Schulte et al. 2019; Baddeley et al. 2012; Honkanen et al. 2019). At the level of motion-sensitive wide-field neurons, the spatial landmark constellation that guides bees to their goal could be shown to lead to a characteristic time-dependent response profile during the intersaccadic intervals of navigation flights providing unique information about the vicinity of the goal (Mertes et al. 2014; Egelhaaf et al. 2014).

- **Estimation of Travelled Distance** Optic flow information is also used at least by bees for spatial tasks in the context of navigation over long distances away from their nest location, such as for the estimation of distances travelled during flights. Bees acquire distance (and direction) information on foraging excursions in an unknown environment to be able to return to their nest and to communicate the location of rewarding food sources to their fellow foragers. They gauge distance in terms of the optic flow experienced during the flight to a food source and use this information (in addition to direction information) during their return flights. Since the optic flow generated during translational movements depends on the three-dimensional layout of the environment, distance information gathered in this way is ambiguous. These ambiguities do not lead to problems as long as the recruited bees tend to fly on the same route as the forager and the environment does not change much between the flight of the forager and that of recruited bees (Fig. 10). Since distinctive changes in the spatial layout of the environment occur only rarely in natural settings over a couple of days, such a relatively simple mechanism of distance estimation is likely to be sufficient for the specific needs of navigating bees under normal behavioral conditions (Srinivasan 2011; Wolf 2011).

Visual Processing in Free Flight, Fig. 10 Honeybees measure distances in terms of optic flow generated during flight and communicate this information to their hive mates by the waggle dance. Behavioral analysis revealed how honeybees estimate the distance travelled between their hive and a food source. (a) Layout for the experiments using tunnels and probabilities of waggle dance (W; orange bars) and round dance (R; blue bars). A tunnel with a length of 6 m and a width of 11 cm was positioned either at a distance to the hive of 35 m (not drawn to scale) or at a distance of only 6 m. The walls of the tunnel were either covered with a texture that contained vertically oriented (Exp. 1, Exp. 2, Exp. 4) or horizontally aligned stripes (Exp. 3). The bees were trained to collect sugar water from a food source (indicated by red object). When the food source was placed at the entrance of the tunnel (Exp. 1), the bees performed mainly round dances after returning to their hive, signaling a short distance to the food source. When the food source was placed at the end of the tunnel containing vertically oriented texture (Exp. 2), the returning bees performed mainly waggle dances, signaling

much larger distances to the hive, although the actual travel distance was not much larger. A food source at the same distance, however, located in a tunnel with horizontally oriented stripes (Exp. 3), again led mainly to round dances. The main difference between Exp. 2 and Exp. 3 is that in the former, much optic flow is evoked on the eyes of the honeybee while flying along the tunnel, whereas in the latter case, there is only little optic flow, because the contours are oriented along the flight direction. When the tunnel covered with vertical contours and the food source close to its end is placed near to the hive (Exp. 4), mainly waggle dances are performed, which are shorter than those performed in Exp. 2 (compare green bars). These experiments suggest that travelled distance is measured in terms of optic flow. (b) Calibration of the odometer of the bee. Mean duration of waggle dances elicited by outdoor feeders at various distances to the hive. Also shown are the mean durations of waggle dances measured in Exp. 2 and Exp. 4 and their equivalent outdoor flight distances, as read from the regression line. (Adapted from Srinivasan et al. 2000)

Visual Motion as a Source for Information About Other Moving Objects

In some free-flight situations, retinal image motion does not originate primarily from the self-motion of the animal relative to a largely stationary environment but from other moving objects.

- **Escape from Impending Collisions with Moving Objects** Objects that may elicit an escape from an impending collision are not necessarily stationary in the environment.

Rather they may also move toward the animal. Examples are predators but also conspecifics in a swarm. The size of the retinal image of an object increases in a characteristic way when it directly approaches the animal. Under the simplifying assumption that the object moves on a straight collision course at a constant velocity, the temporal dynamics of its retinal image can be fully characterized by its size-to-speed ratio (see above; Fig. 3). For a given object size, a faster approach velocity implies a faster expansion rate and a smaller size-

to-speed ratio. In the locust, but also in *Drosophila*, escape behavior has been concluded not to occur at a fixed time before collision but rather at a fixed delay after the stimulus reaches a threshold angular size on the retina. This could be different in other systems and for other behavioral contexts, where the time it would take for the object to collide with the animal is critical, unless appropriate action is taken (Fotowat and Gabbiani 2011; Dewell and Gabbiani 2018).

There is good evidence, mainly from detailed studies on flight behavior and visual processing in locusts and most recently *Drosophila*, that there is a dedicated pathway in the visual system which is tuned to the characteristics of looming stimuli during an impending collision. The computations performed by the underlying sensory and motor processes could be analyzed in great detail both experimentally and by computational modeling. An identified wide-field neuron plays a key role in the neural circuit. The characteristic time course of its response encodes an impending collision with an approaching object. This information is conveyed via further identified neurons to motor centers that eventually generate escape behavior. The neural mechanisms of the angular threshold computation relevant for collision avoidance rely on three distinct processes: (1) motion-sensitive excitation evoked by the brightness changes resulting from displacements of the approaching object's retinal image activating retinotopically a dendritic subfield of the wide-field neuron, (2) an inhibitory network acting onto the motion-sensitive pathway presynaptically to the wide-field neuron, and (3) feedforward inhibition impinging on two additional dendritic subfields of the wide-field neuron. Eventually, the wide-field neuron's output performs a kind of multiplication by a nonlinear transformation of the overall postsynaptic potential into spike activity. This multiplication of an input that depends on the size of the approaching object with another input that depends on angular velocity of the edges of the object has been concluded to be

decisive in computing object approach (Fotowat and Gabbiani 2011; Dewell and Gabbiani 2018).

- **Pursuit of a Moving Target** Many insects follow moving objects, such as potential prey or mates. Dragonflies pursue other insects in highly aerobatic flight maneuvers to catch and eventually eat them. They appear to compute an interception course which somehow requires prediction of the moving target's future locations. In their third visual neuropile, neurons that are sensitive to small objects in restricted parts of the visual field have been characterized electrophysiologically and modeled. The outputs of such small target-selective local neurons are pooled by a population of individually identified descending neurons which have been concluded to represent a vector that reflects the direction of target motion with high accuracy (Gonzalez-Bellido et al. 2016; Olberg 2011; Nordström 2012).

In the context of mating behavior, male blow- and houseflies chase females in aerobic visually controlled flight maneuvers. The forward velocity of the chasing fly is controlled by the angular size of the target, whereas the turning velocity depends on the angle from which the target is seen as well as on its speed. The pursuing fly generates catch-up saccades when the target changes its direction too rapidly for the pursuer to follow smoothly. Pursuit of moving objects is, so far, the only flight behavior described in detail where, at least in flies, no clear flight phases characterized by almost pure translational movements are observed. During their rapid pursuit maneuvers, male flies, thus, abandon the possibility to gather information about the environment apart from information about their moving target. This may be functional given the fact that when closely following the course of its moving target, the pursuing fly will hardly collide with stationary obstacles in its surroundings. Accordingly, the gain of the optomotor course stabilizing system (see above) appears to be much reduced while the male fly is chasing (Egelhaaf et al. 2012; Trischler et al. 2010).

Constraints Imposed on Visual Information Processing by a Timescale of Natural Behavior

During free flight the retinal motion patterns continually change. As a consequence of the typical saccadic flight and gaze strategy of insects (see above), optic flow dynamics during natural locomotion deviate considerably from motion stimuli (e.g., constant velocity motion, white-noise velocity fluctuations) that are often employed when characterizing neural computations. In the context of spatial vision, the translatory flight segments and especially the intersaccadic intervals are the most likely times during which the flying insect can gather information about the spatial layout of the outside world. Although intersaccadic intervals have the largest share of the entire flight time, they may be as short as 30 ms. Hence, information processing during free flight needs to take place on very short timescales. Rapid information processing is not only an issue in the context of intersaccadic spatial vision but often highly relevant when the flying insect encounters moving objects and has to respond to them in an appropriate way (i.e., either escape or pursue; see above).

Why is rapid information processing during flight and the short timescales during which information about the environment needs to be computed an issue at all? One reason is that neurons are relatively unreliable computing devices. In insects the problem of reliability is particularly daunting, as there is not much redundancy at the output level of the visual system which would allow for the pooling of information across equivalent neurons (de Ruyter van Steveninck and Bialek 1995; Warzecha et al. 2013; Warzecha and Egelhaaf 2001).

When the same stimulus is repeatedly presented to a neuron, the responses may vary much between trials. Neuronal activity continually fluctuates even during constant velocity motion. On the basis of individual response traces, it is not easily possible to discern stimulus-driven activity changes from those that are due to sources not associated with the stimulus (“noise”). The origin of various potential noise sources in the visual motion pathway and the consequences of the

unreliable nature of neural signals can be attributed in part to the input of the visual system, i.e., photon noise, but arise mainly from a host of biophysical and cellular processes in the nervous system. Examples of such noise sources are the mechanisms involved in synaptic transmission and action potential generation. The impact of these noise sources on the precision with which motion information can be encoded is still not entirely clear. However, one aspect that appears to be especially relevant in the context of computing spatial information during intersaccadic intervals could be resolved to some extent: Given that neuronal responses are noisy, it will take some time to reliably infer behaviorally relevant environmental information from neuronal activity. Statistical analyses of noisy intersaccadic responses of individual and populations of fly wide-field neurons in the third visual neuropile reveal that sufficiently reliable information about translatory self-motion and, thus, about spatial parameters of the environment can already be decoded on a timescale of little more than 5 ms and, thus, on a timescale relevant for processing behaviorally relevant information (Egelhaaf et al. 2005).

Conclusions

Vision is only one information source for behavioral control in free flight. Other sensory modalities, especially a wide variety of mechanosensors, are also important, for instance, for stabilizing the attitude of the animal (Hengstenberg 1993; Frye 2010; Sane 2016; Dickinson and Muijres 2016). However, behavior is a phenomenon that takes place in space and is intricately entangled with it. Thus, its control requires information about its environment, which to a large extent can only be provided by the visual system. It is safe to conclude that flying insects, such as flies, bees, locusts, and dragonflies, rely primarily on their visual system to perform their highly aerobatic flight maneuvers and to solve complex spatial tasks, such as avoiding collisions with obstacles, negotiating gaps, landing on objects, or even finding hardly visible goals on the basis of spatial

landmark information, but also to detect and pursue other moving insects that may serve, for instance, as a prey or a mate. Insects accomplish all this with the help of tiny brains with less than a million neurons and a spatial resolution of their eyes much smaller than technical camera systems. Hence, if resource efficiency with respect to computational effort and energy consumption is conceived as a benchmark, insects outperform man-made autonomous flying systems in the abovementioned tasks. Moreover, insects successfully solve these tasks at flight velocities that imply rapid time-varying image flow on their eyes. The processing of the fast retinal image flow presents the neuronal machinery with great challenges in view of the limited reliability of neurons as computing devices. Obviously, as a consequence of millions of years of evolution, insect nervous systems have become well adapted to successfully cope with these computational challenges and to solve those computational tasks that are relevant for the success of the species efficiently and parsimoniously.

One way to achieve such exceptional performance is for insects to actively shape the image flow on their eyes by their characteristic flight behavior, for instance, by segregating through a saccadic flight and gaze strategy their translational and rotational movements and, thus, the corresponding optic flow components on their eyes. In this way neural processing of spatial information about surfaces and objects in the environment is greatly facilitated. More generally, and also taking into account other behavioral contexts, such as the encounter with other moving animals, it is suggested that by tuning the neural networks for visual information processing to the characteristic spatiotemporal properties of the retinal motion patterns as generated during free flight allows the nervous system to solve apparently complex vision tasks efficiently and parsimoniously.

Most conclusions on how visual information is processed in free flight are based on electrophysiological experiments performed on completely restrained animals because recording from most of the analyzed cells has not been possible during flight. In some recent analyses,

conventional experimenter-defined visual stimulation was abandoned. Instead, analyses at the neuronal level were carried out by simulating the complex spatiotemporal visual stimulus conditions during free flight and presenting the tethered animal motion sequences that free-flying animals had previously experienced in various behavioral contexts. From this type of experiment, it has been possible to draw conclusions about the significance of intersaccadic neuronal responses for providing the animal with spatial information (Egelhaaf et al. 2012; Kern et al. 2012). Although recent studies suggest that the overall behavioral state of the animal influences motion-sensitive wide-field neurons at the output level of the visual system by increasing their response level and slightly shifting their velocity tuning (Maimon 2011), the overall specificity of these neurons to different optic flow patterns and, thus, the major conclusions on visual processing in free flight appear not to be affected (Egelhaaf et al. 2012; Rien et al. 2013). However, the output signals of these neurons may be affected in a highly specific way by motor-related inputs, which quantitatively silence the predicted visual responses to rotations around the relevant axis while preserving sensitivity to “unexpected” visual input (Kim et al. 2017). This kind of efference copy signal, thus, can be expected to reduce the responses of motion-sensitive wide-field neurons to the rotational optic flow during saccadic turns while leaving the cell fully responsive to the optic flow perceived during intersaccadic intervals. This kind of behavioral modulation of visual signals would thus further facilitate optic flow-based spatial vision. While all the above conclusions about the impact of the behavioral state on visual information processing were based on tethered flying or walking animals, recent successful attempts to monitor neural activity at least in large free-flying insects (i.e., locusts, dragonflies) show great promise to challenge these conclusions in more natural conditions (Harrison et al. 2011; Yue et al. 2018).

In any case, it is reasonable to conclude from the experimental work on visually guided free-flight behavior of insects and the underlying neural mechanisms that insects with their tiny brains

derive part of their power as autonomous systems from dynamic animal-environment interactions that lead to adaptive behavior in environments of a wide range of complexity. Model simulations and robotic implementations reveal that the smart biological mechanisms of motion computation and flight control might be helpful when designing micro air vehicles that may carry an onboard processor of only relatively small size and weight (Floreano et al. 2009).

Visual Prosthesis

► Visual Prosthesis, Optic Nerve Approaches

Visual Prosthesis, Cortical Devices

Eduardo Fernandez

Department of Histology and Institute of Bioengineering, University Miguel Hernández, Elche, Spain

Synonyms

Intracortical microelectrodes for visual rehabilitation; Visual cortical implants; Visual neuroprosthesis

Definition

Cortical prostheses are a subgroup of visual neuroprostheses capable of eliciting visual percepts in profoundly blind people through direct stimulation of the visual part of the brain. This approach is the only treatment available for blindness caused by glaucoma, optic atrophy, or by diseases of the central visual pathways such as brain injuries or stroke.

Detailed Description

As blindness results from an interruption in the normal flow of signals along the visual pathways, a visual prosthesis has to excite the neurons of the pathway at some point after the damage site (Normann et al. 1996). The only requirement is that the device should contact with still functioning neural elements. Since retinal diseases frequently reduce visual acuity and result in non-curable blindness, several groups worldwide are working on the development of different

prostheses designed to interact with the remaining healthy retina, optic nerve, and lateral geniculate nucleus (LGN) (Fernandez and Hofmann 2011; Dagnelie 2012; Fernandes et al. 2012; Guenther et al. 2012; Shepherd et al. 2013). However, the output neurons of the eye, the ganglion cells, often degenerate in many retinal blindnesses (Marc et al. 2008), and therefore, a retinal, an optic nerve, or even an LGN prosthesis would not be always helpful. This extensive degeneration usually spares the neurons in the higher visual regions of the brain, highlighting the enormous potential of a cortical prosthesis designed to stimulate cortical neurons (Troyk et al. 2003; Fernandez et al. 2005; Normann et al. 2009; Tehovnik and Slocum 2013). Thus, if these higher visual centers could be stimulated with visual information in a format somewhat similar to the way they were stimulated before the onset of blindness, a blind individual could be able to use this stimulation to extract

information about the physical world around him/her.

Figure 1 illustrates the basic components of this approach. One or two cameras provide image acquisition, which is then processed by a bioinspired retina-like encoder in order to transform the visual world into electrical signals (Morillas et al. 2007). This first stage performs a multichannel spatiotemporal filtering to extract and enhance the most relevant features of the scene and also re-encodes this information into a neuromorphic stream of electrode addresses. The second stage serializes the information and transmits it through a radio-frequency (RF) link to the implanted device. This RF block provides a wireless transfer of power and data to the internal system. The implanted electronics package must decode the signals, identifying the target electrodes and stimulus waveform applied to the corresponding electrodes located near the target

Visual Prosthesis, Cortical Devices, Fig. 1 Basic components of a cortical visual neuroprosthesis

neurons (Romero et al. 2007; Rush and Troyk 2012).

While the full restoration of vision seems to be impossible, it is expected that a cortical device can create truly meaningful visual percepts that can be translated into functional gains such as the recognition, localization, and grasping of objects or skillful navigation in familiar or unfamiliar environments resulting in a substantial improvement in the standard of living of visually impaired persons.

The Case for a Cortical Visual Neuroprosthesis

The concept of a cortical visual prosthesis began with studies of the functional architecture of the cerebral cortex and has a long history in biomedical engineering. A German neurosurgeon, Foerster, was the first to expose the human occipital pole under local anesthesia and to electrically stimulate it (Foerster 1929). He noted that electrical stimulation induced the perception of points of light, called phosphenes and usually described as “stars in the sky,” “clouds,” and “pinwheels” that were dependent on where the stimulation probe was placed. These findings together with the earlier studies of Wilder Penfield and coworkers during the course of neurosurgical interventions for the treatment of epilepsy (Penfield and Rasmussen 1950) settled the physiological basis for present efforts to develop a visual prosthesis for the blind.

Subsequent experiments by the group of Giles Brindley in England, William Dohelle at the University of Utah, and others showed that stimulation of multiple electrodes simultaneously allowed blind volunteers to recognize simple patterns, including letters and Braille characters (Brindley and Lewin 1968; Dohelle et al. 1976; Dohelle 2000). Unfortunately, these early efforts did not culminate in the restoration of a useful visual sense. Problems with this early work were associated mainly with the large-surface electrodes that were used to evoke phosphenes. Thus, relatively high electrical currents were required to evoke phosphenes, and when multiple

electrodes were stimulated, these large currents could interact in a nonlinear fashion, evoking phosphenes with unpredictable spatial properties. Furthermore, they also found that a visual prosthesis based on relatively large-surface electrodes implanted subdurally would have limited usefulness because of occasional elicitation of pain due to meningeal or scalp stimulation and the risk of inducing epileptic seizures.

A promising approach, which can activate populations of neurons with greater spatial specificity and lower levels of stimulation than is possible with larger electrodes on the surface of the brain, is the use of intracortical microelectrodes (Schmidt et al. 1996).

Selection of Suitable Subjects for a Cortical Visual Prosthesis

The selection of a specific person for a cortical visual implant is not straightforward, and currently there are no strict standardized criteria for accepting or rejecting a candidate nor for the best rehabilitation procedure for every type of blindness (Merabet et al. 2007).

In general it is considered crucial that the subject should have at best bare light perception and have no significant benefit from a conventional visual aid. Furthermore, previous visual experience is needed. In this context, it has been presumed that if blindness occurs after the age of 10 years, visual pathways should develop normally and thus remain Excitable.

Advantages of the Approach

Penetrating arrays of microelectrodes have been successfully used in long-term animal studies, and the skull provides a stable and rugged housing for the implant. Furthermore, this approach provides a potential solution to pathologies affecting the entire retina, optic nerve, thalamus, or brain. Thus, it is the only treatment available for blindness caused by glaucoma or optic atrophy as well as for diseases of the central visual pathways such as brain injuries or stroke.

Limitations

The main problem of a cortical implant is the lack of preliminary processing by the brain, particularly in the retina where much of the information reduction takes place. Some other impediments are related with the development and implementation of strategies designed to interface with a visually deprived brain that can be specifically tailored for the own needs of each patient.

On the other hand, cortical prosthesis must be implanted into the nervous system and remain fully functional for periods that will eventually extend to many decades. Therefore, these devices must be highly biocompatible and be able to resist the attack of biological fluids, proteases, macrophages, or any substances of metabolism (Marin and Fernandez 2010). Likewise, it is necessary to take into account the possible damage of neural tissues by permanent charge injection. These considerations place unique constraints on the architecture, materials, and surgical techniques used in the implementation of a cortical prosthesis (Normann et al. 1999).

Challenges and Future Perspectives

A key issue that has often been utterly underrated in the field of visual prosthesis is the role of neural plasticity. Thus, a helpful visual prosthesis should take into consideration not only standardized methods and employ current clinical and technological expertise but also consider newly emerging developmental and neurophysiological evidence. For example, there is considerable evidence that adaptive and compensatory changes occur within the brain following the loss of sight (Fernandez and Merabet 2011; Merabet 2011). The modulation and understanding of these neuroplastic processes are crucial for the success of any visual neuroprosthesis and can provide useful strategies for improved rehabilitation and teaching methods for the blind.

Other future challenges are related with the development of advanced bidirectional interfaces with the human nervous system.

Definition

An electronic system, usually comprised of external and implanted components, that can sense light, convert light to an electronic signal, and apply that signal to the retina, as a treatment for blindness secondary to photoreceptor loss.

Detailed Description

In a healthy retina, light is detected by photoreceptors (rods and cones) via photosensitive molecules in the outer segments of the photoreceptors. These molecules, once transformed by light, trigger a cascade of neurochemical events that lead to other neural cells in the retina (ganglion cells) sending signals to the downstream visual centers of the brain. Retinal degenerative diseases, like retinitis pigmentosa and age-related macular degeneration, affect primarily photoreceptors, leaving the retina unable to sense light, but remaining neurons in the retina (bipolar cells and ganglion cells) can be electrically activated, based on established techniques for nerve stimulation.

A typical retinal prosthesis has multiple components each with a specific function (Fig. 1). These include an imager to convert light to electrical signal, electronics to process and condition the image and generate electrical stimulus pulses, and an array of microelectrodes to stimulate the retina. Other important components found in one form or another on most implants include hermetic packaging and wireless data/power transmission. However, retinal prostheses are often categorized based on the location of the electrode array, which forms the functional interface with the retina. The locations where an electrode array can be implanted to stimulate the retina include epiretinal (on the top surface of the retina), subretinal (under the retina), and suprachoroidal (between the sclera and choroid).

Several prototype systems of chronic implantable devices have been tested in clinical trials. These fall into two types of implants. The first type of device was designed to show feasibility in humans, but not intended to be a commercially viable medical device. Thus, the main concern for these devices was patient safety and they generally were not refined to the same degree as a commercial product. For example, a number of these early chronic implants could only be activated when the patient visited the clinic. The second type of devices is intended as commercial devices, so they are engineered not only for robustness and safety but also to have expected longevity of over a decade and with human factor

Visual Prosthesis, Epiretinal Devices, Fig. 1 Retinal prosthesis concept: an external camera captures and image. Wireless transmission of image data to an implant specifies

the stimulation pattern that is applied to the retina via a microelectrode array

considerations. One device, the Argus II retinal prosthesis (Second Sight Medical Products, Inc.), has received approval in both Europe and the United States to be sold as a treatment for retinitis pigmentosa. A summary of current and past clinical trials of retinal implants can be found at www.clinicaltrials.gov; search “retinal prosthesis.”

Epiretinal implants involved in feasibility studies include the Argus I from Second Sight and devices from Intelligent Medical Implants, GmbH (IMI) and the Epi-Ret Consortium (Epi-Ret). All three of these systems used wireless power and data delivery (to avoid transcutaneous wires).

The Argus I device was implanted in six subjects between 2002 and 2004 (de Balthasar et al. 2008). Argus I was a modified cochlear implant. As such, the electronics were implanted behind the ear, and a cable run along the temple, into the orbit, and, finally, into the eye, terminating in a

4×4 grid of platinum electrodes, either 520 mm or 260 mm diameter. With training, subjects were able to distinguish objects from a small set and detect motion of a moving bar. Subjects have been implanted for as long as 8 years with the device still functional.

The IMI device was implanted in a total of seven subjects (Hornig et al. 2007). This device utilized a microfabricated array with a total of 49 electrodes. The implant was entirely in the orbit, with the electronics module on the outside of the eye and the electrode array in the eye (via a cable across the eye wall). This system could only be activated in the clinic as no camera system was available. Using this device, subjects could see spots of light and some simple patterns. Since the electronics were not hermetically packaged, but only sealed with polymer coatings, the implants were removed after several months or, in one case, 1.5 years.

The Epi-Ret device was implanted in six patients (Klauke et al. 2011). The stimulating array had 25 electrodes and also was miniaturized to the point where the entire device could be implanted in the eye. A unique feature of the stimulating array was protruding electrodes, which improved contact with the retina and resulted in low perceptual thresholds. Like the IMI device, the Epi-Ret system was designed only for semichronic implantation (4 weeks) and did not have a camera system so the implant could only be activated in the clinic.

Commercial Design

Approval to sell a medical device as a treatment for a specific disease is only granted after approval by government agencies. The Argus II epiretinal prosthesis has received approval in Europe and the United States. The Argus II is similar to the IMI device in that the electronics are on the outside of the eye and the electrode array is on the retina, connected by a cable across the eyewall to the electronics (Humayun et al. 2012). The Argus II, however, has a camera system that provides input to the implant and the electronics are protected with a hermetic package so that implant longevity is decades. Thus, patients with implants can leave the clinic with the system. Sixty electrodes are arranged in a 6×10 format.

Thirty subjects were enrolled between 2007 and 2009. All subjects were able to perceive light during electrical stimulation. Other tasks on which subjects performed well include object localization and motion detection. Letter reading was tested in 22/30 subjects (da Cruz et al. 2013). Six of these subjects were able to identify any letter of the alphabet at a 63.5% success rate (vs. 9.5% with the system off). In all 22 subjects, a small set of eight letters was identified 72.5% correctly vs. 16.8% with the system off. Subjects were free to take as much time as needed to make a judgment. Adverse events that occurred during the trial included low eye pressure and infection, but such events decreased in later implants.

Conclusion

Epiretinal prostheses have proven that they have the capability to improve the lives of people blind from retinal degenerative disease. Multiple systems have been tested in humans, with one device receiving approval for sale.

Definition

An optic nerve-based visual prosthesis is one type of viable visual prosthetic device, potentially allowing those with profound vision loss to have a usable level of vision. Visual impairment usually arises from degenerative diseases such as retinitis pigmentosa (RP) and age-related macular degeneration (AMD). An implantable microelectronic device can be used to electrically stimulate the optic nerve with surface or penetrating electrodes for vision recovery. The axon bundles could be stimulated and a larger visual field produced than through other approaches such as visual cortex prostheses and retinal prostheses.

Detailed Description

Since the human brain is extremely intricate and fragile, surgically implanting electrode arrays poses a high risk to the visual cortex. Although visual cortex prostheses were put forward firstly, it has always imposed great psychological pressure on the patient. A visual prosthesis based on a retinal placement is currently the most widely adopted approach for vision restoration (Zrenner 2002; Humayun et al. 2003; Rizzo and Wyatt 1997). The channels of micro-current stimulators as well as the density of microelectrode arrays are, however, limited by current technology. It is not possible to provide high spatial resolution by covering a large area of the retina with present implantable device technologies and microelectrode array fabrication techniques.

Visual information is transmitted via the optic nerve which is composed of the axonal process from millions of retinal ganglion cells. Thus, this makes a visual prosthesis based on optic nerve electrical stimulation a reasonable approach for vision restoration. Compared with a retinal prosthesis, it is possible to provide more meaningful visual cues by applying the same amount of electrodes to the optic nerve. A contact spiral cuff electrode has been designed for optic nerve stimulation (Veraart et al. 1998). However, the spatial resolution of the recovered vision was limited due to the fact that surface-stimulating electrodes were

used. In order to improve the spatial resolution, penetrating microelectrode arrays have been invasively inserted into the optic nerve (Ren et al. 2007; Chai et al. 2008; Sui et al. 2009). With advanced processing techniques, the size of the microelectrode arrays may be minimized greatly, resulting in reduced optic nerve damage and high spatial resolution. Compared with many retinal prostheses, an optic nerve visual prosthesis has a significant advantage in that the surgical approaches are considerably simple and there is no need to breach the scleral wall. The Chinese Project for Sight (C-Sight) is an interdisciplinary group project with the aim of developing this type of visual prosthesis.

Hardware Structure of the C-Sight Prosthesis System

The visual prosthesis from C-Sight consisted of external and implantable parts. The external part included image capturing, processing, and wireless communications. The visual scene was captured by a CMOS camera which was mounted at the center of a set of glasses. The processed visual information was encoded into trains of digital signals with a specific spatiotemporal stimulation pattern by a neural electrical stimulator and forwarded by radio transmission. An implanted neurostimulator received the radio signals and after decoding was used to activate various channels of an implanted multichannel penetrating microelectrode array configured as a 3-by-6 grid of penetrating electrodes.

In vivo Electrophysiological Study on Electro-Neural Tissue Interface

In vivo experiments conducted in rabbits and cats by the C-sight group showed that visuotopic stimulation could be achieved by an optic nerve implant. Low-threshold, localized, and discriminable stimulation could be achieved by using appropriate stimulating modes, waveforms, electrode size, interelectrode distance, and electrode distribution. Electrically evoked potentials (EEPs)

could be elicited by optic nerve stimulation. Current stimuli with cathodic-first pulses in a monopolar mode could elicit up to $1 \sim 2^\circ$ localized cortical responses. Two electrodes with inter-distance of $150 \mu\text{m}$ along the optic nerve axis could elicit discriminable cortical responses with a spatial resolution of $2\text{--}3^\circ$ (Sun et al. 2011).

Psychophysical Study Using Simulated Phosphenes

Due to the limited number of electrodes eliciting limited discrete phosphenes, one of the most important problems is how to provide the most useful visual information to prosthesis wearers. Therefore, it is significant to study the minimal information requirement and optimization of artificial vision based on simulated prosthetic vision. The simulated prosthetic vision processor consists of image acquisition and processing, a phosphene processor, and a simulated prosthetic vision renderer.

A precise description of phosphene characteristics (mapping, size, and so on) plays an important role in determining image processing for visual prostheses. Psychophysical experiment results demonstrated that combined training using tactile information and visual prosthetic stimulation may be potentially useful when training blind subjects to estimate phosphene characteristics. Simulated object recognition experiments showed that resolution, distortion, and dropout had a significant impact on the performance of the visual tasks.

Optic Nerve Exposure Surgery for Visual Prosthesis Implantation

The exposed space of the optic nerve is limited during surgery. After many animal experiments, the conclusion was drawn that the exposure of the optic nerve through stripping of the surrounding tissue around the eyeball is not desirable. To this end, our group proposed a novel, more feasible surgery solution based on tissue stripping in combination with craniofacial surgery. In brief, a high-

resolution, preoperative CT image of the eye is made in order to evaluate the incision size of the zygomatic bone on the temporal side of the eye socket. During the surgery, the zygomatic bone is cut and the orbital soft tissue is moved to maximize the available surgery space. The microelectrode array is permanently implanted in the optic nerve, with the array's wiring fixed to the orbital muscle. The removed section of zygomatic bone will be returned to its original position after the array is successfully implanted.

Definition

Retinal degenerative diseases lead to blindness due to loss of the “image capturing” photoreceptors, while the “image processing” inner retinal neurons and the “output” ganglion cells are relatively well preserved. Electronic retinal prostheses seek to reintroduce visual information and thereby restore sight by patterned electrical stimulation of the surviving neurons.

Detailed Description

Photoreceptors convert light into neural signals, which are processed by the inner retinal neurons, leading to generation of action potentials in the retinal ganglion cells (RGCs). These signals travel through the optic nerve to the brain and serve as the basis for visual perception. In retinal degenerative diseases, such as Retinitis Pigmentosa or Age-Related Macular Degeneration, photoreceptors gradually disappear, leading to loss of sight, even though the inner retinal cells remain largely intact. Electrical stimulation of the remaining retinal neurons can reintroduce visual information, creating patterned percepts of light, called phosphenes.

Retinal implants are usually classified into epiretinal, subretinal, and suprachoroidal, according to their anatomical placement in the eye. In the *epiretinal* approach (Ahuja et al. 2013), stimulating array is placed on top of the

retinal surface and typically targets the ganglion cells (RGC), as shown in Fig. 1b. Epiretinal arrays can be implanted with relative ease and can also be removed in case of postsurgical complications or device failure. The ultimate goal of direct stimulation of RGCs is to emulate the natural retinal code (Jepson et al. 2013). Rapid (1–3 ms) response of RGCs to electrical stimulus with a single action potential enables precise control of the elicited spikes sequence (Grosberg et al. 2017). Since different types of ganglion cells respond to different aspects of the image (increase or decrease in light, direction of motion, etc.), they require different encoding of the visual information. Identification of cell types in diseased retina and selective activation of them is very challenging. Another problem with epiretinal electrodes is that they stimulate not only the nearby cells, but also the axons from distant cells passing underneath the electrodes (Grosberg et al. 2017). Consequently, patients report distorted arcuate visual percepts instead of round localized spots (Nanduri et al. 2012).

In the *subretinal* approach, electrodes are located underneath the inner nuclear layer, replacing the degenerated photoreceptors (Fig. 1b, Stingl et al. 2013; Lorach et al. 2015). Graded responses induced in the inner retinal neurons by electrical stimulation are transmitted via the retinal network to the ganglion cells, which convert them into bursts of action potentials. This way, part of the retinal signal processing is preserved and encoding of the visual information by subretinal implant is simplified, compared to the binary encoding of the output spikes in RGCs using epiretinal implants. Preserved features include flicker fusion at high frequencies (Lorach et al. 2015), antagonistic center-surround organization (Ho et al. 2017), and nonlinear summation of subunits in receptive fields (Lorach et al. 2015), as well as ON and OFF responses (Ho et al. 2018). Subretinal placement also provides very close and stable proximity of electrodes to the target neurons, while epiretinal implants often float above the retina and shift over time. However, implantation in the subretinal space can be more difficult than on epiretinal side, and removal of the implant is also more challenging.

Visual Prosthesis, Optoelectronic Devices,

Fig. 1 Placement of the retinal stimulation arrays. (a) Histological cross-section of a healthy rat retina. Signal generated in photoreceptors (PR) is processed in neurons of the inner nuclear layer (INL) and then in the retinal ganglion cells (RGC), which generate action potentials

(spikes) that propagate via the retinal nerve fiber layer (RNFL) to the brain. (b) Epiretinal implants are placed on top of the nerve fiber layer, while subretinal implants replace photoreceptors in a degenerate rat retina, facing the inner nuclear layer. Suprachoroidal implants are placed between the choroid and the sclera. Scale bar: 50 μm

In *suprachoroidal* approach, the implant is placed between the choroid and the sclera, the hard shell that encapsulates the eye (Fig. 1b). Larger distance between stimulating electrodes and retinal neurons greatly restricts attainable spatial resolution in this approach. Therefore, such implants are designed to help with low-resolution peripheral vision, primarily for ambulation (Ayton et al. 2014).

Another major distinction is the way information and power are delivered to the implant:

(A) In ARGUS II (Second Sight Inc. Sylmar, CA), information from a head-mounted camera, as well as power, are transmitted to the implant via an RF antenna (Ahuja et al. 2013). The signals are decoded and processed inside the extraocular implant, before being delivered to the 6×10 stimulating electrode array via a trans-scleral cable. A flexible foil with an array of 200 μm electrodes spaced by 575 μm is attached to the epiretinal surface with a trans-retinal tack. The Argus II has now been implanted in more than 200 patients, with a best grating visual acuity of 20/1260 (Ho et al. 2015). The device tends to improve patients' spatial mobility, despite its low resolution. Disconnect between the visual information

transmitted to the implant and the eye movements creates a perceptual mismatch since the brain expects the images to shift on the retina during eye movements. In principle, this issue can be rectified using eye tracking to electronically shift the image transmitted to the implant. Suprachoroidal RF-powered devices developed and implanted by Bionic Vision Australia (three patients (Ayton et al. 2014)) and by Osaka University (two patients (Fujikado et al. 2011)) have even larger electrode spacing (2 mm), so that the equivalent visual acuity is in the range of 20/4000 to 20/20,000.

(B) In the Alpha AMS prosthesis (Retina Implant AG, Reutlingen, Germany) (Stingl et al. 2013), a subretinal camera consisting of 1600 pixels of 70 μm in size converts natural images on the retina into electrical currents that stimulate neurons in the inner nuclear layer. Power is delivered to the implant via a trans-scleral cable connected to an RF power receiver positioned behind the ear, like in cochlear implants. Optical transmission of the images retains the natural coupling between the visual information and the eye movements. Typically, visual acuity with this device is no better than 20/1200 (Zrenner et al. 2011), but a few

Visual Prosthesis, Optoelectronic Devices,

Fig. 2 Simplified diagram of the photovoltaic retinal prosthesis (PRIMA).

Images captured by a camera are displayed in the video goggles and projected onto the retina using pulsed near-infrared (880 nm) light. Pixels in the subretinal photodiode array convert this pulsed light into electric current flowing through the tissue and stimulating the nearby neurons

patients demonstrated acuity up to 20/550 (Stingl et al. 2015).

- (C) In the PRIMA system (Pixium Vision, Paris, France) (Lorach et al. 2015), images captured by the head-mounted camera are projected onto the retina from augmented-reality goggles using pulsed near-infrared (~ 880 nm) light (Fig. 2). Wireless photovoltaic subretinal prosthesis directly converts light into pulsed electric current in each pixel, stimulating the nearby neurons. Preclinical studies with $70\text{ }\mu\text{m}$ pixels demonstrated grating visual acuity matching the pixel pitch. Clinical study with patients blinded by geographic atrophy started in 2018. It demonstrated safety of subretinal implantation of the 2 mm wide $30\text{ }\mu\text{m}$ thin chips, and bright visual percepts in retinotopically correct locations within the former scotoma. Measurements of the visual acuity are in progress. In the future versions of the implant, the pixel pitch is expected to decrease below $50\text{ }\mu\text{m}$, to provide visual acuity above the threshold of legal blindness (20/200).

Definition

A visual prosthesis is a device which can artificially restore vision to blind patients. The optogenetic approach involves reverse engineering remaining pathways in the visual system to be photosensitive with light-activated pumps and channels. Illuminating these with optoelectronics encoding visual scenes can then return a sense of vision.

Detailed Description

The human visual system consists of the eye, the optic nerve, and the visual processing centers in the thalamus and visual cortex of the brain. The eye is responsible for optics, image stabilization, transduction and acquisition, with the latter two occurring in the retina. Retinal ganglion cells (RGCs) send information from the eye to the thalamus, which is responsible for sorting left and right eye information. The final projection is to the visual cortex which reconstructs the information to allow the individual to recognize their environment.

Any damage to this sophisticated but delicate system through trauma or disease will impair subsequent vision. Globally, there are 285 million sufferers of visual impairment, of which almost 40 million are blind (WHO 2012). The Royal

National Institute for Blind People, UK, estimates Two-thirds of registered blind and partially sighted people of working age are not in paid employment (RNIB 2012).

Despite increasing availability of retinal pharmaceuticals, there is presently no treatment for those with retinitis pigmentosa (RP), which causes degeneration of the light-sensing rod and cone cells. For those that have become completely blinded by this condition, a retinal prosthesis holds strong promise for visual restoration. For those with a damaged optic nerve (i.e., *glaucoma* or trauma), a more invasive thalamic or visual cortical prosthesis is required. At the time of writing, electronic retinal implants capable of returning rudimentary vision are commercially available, and there are a number of groups investigating optogenetic approaches to both retinal and visual cortical prosthesis. The scheme of such systems can be seen in Figs. 1 and 2.

History

The “stars” that are seen when the head is struck is due to mechanical stimulation of the visual cortex as it hits the back of the skull. Such “phosphenes” are reported in the literature as far back as the fifth century BC (Grüsser and Hagner 1990) and may have been pondered upon by those who had lost vision. Early attempts at vision restoration started in 1929 when Förster showed that electrical stimulation of the visual cortex could elicit phosphenes (Förster 1929). This was followed up in 1968 by Brindley (Brindley and Lewin 1968) and Dobelle (Dobelle et al. 1974) in the 1960s and 1970s. Many practical difficulties then effectively stopped further progress. Then in 1992 Stone and coworkers (Stone et al. 1992) discovered that patients with RP still had functioning RGCs in their retinæ. Subsequently, the dominant focus of the visual prosthesis community shifted to retinal prosthesis. After two decades of effort, the first retinal prosthesis became commercially available in 2012 with 60 stimulating electrodes.

In 2003 a group investigating the basic properties of algae demonstrated optical

Visual Prosthesis, Optogenetic Approaches, Fig. 1 The main concept of visual prosthesis. The prosthesis conceptually consists of image acquisition (camera), image processing (mobile phone processor), a stimulator (electrode array or optoelectronic array), and some form of

power transmission such as RF. Target areas for stimulation are then either the retina, the optic nerve, the lateral geniculate nucleus (visual part of the thalamus), or the visual cortex

depolarization of cells by genetically incorporating a photosensitive ion channel called channelrhodopsin (Nagel et al. 2003). Later in 2007 (Zhang et al. 2007) it was shown that light-activated chlorine pumps could be used to hyperpolarize cells. The two approaches – allowing full control of neural activity of neuron cells by genetically expressing light-activated channels and pumps in their membranes – became known as “optogenetics.” The key advantage of this technique over previous electronic approaches is that it allows for specific targeting of neural sub-circuits – allowing much more control over the transmission of neural code. Additional advantages include the ability to both stimulate and inhibit and durability as there are no stimulating electrodes which can degrade with time.

Expression of channelrhodopsin was first shown in RGCs in 2005 (Bi et al. 2006). Then in 2008 it was shown that selective expression could be achieved in the ON bipolar pathways (Lagali

et al. 2008). The visual system splits information between ON and OFF pathways; thus, the ability to selectively stimulate one over the other is important in restoring high-quality vision. Later in 2010 it was shown that it was possible to reactivate nonfunctional photoreceptors with halorhodopsin (Busskamp et al. 2010). At the time of writing, some initial expression has been achieved in the visual cortex (Lee et al. 2012), but work in this area is still at a preliminary stage.

Optogenetic Retinal Prosthesis

In comparison to electronic prostheses optogenetic forms of retinal prosthesis simply require an injection of a virus to encode channelrhodopsin or halorhodopsin into a target retinal layer: ganglion cells, bipolar cells, or degenerate cone cells. Then rather than implanting, a headset akin to present augmented reality systems could

Visual Prosthesis, Optogenetic Approaches, Fig. 2 Optogenetic retinal prosthesis. In the case of optogenetic retinal prosthesis, a virus is injected into the eye to make one of the remaining cell layers

photosensitive. High-brightness miniature screens using, for example, microLED arrays then project the appropriate stimulating light pattern into the eye

be worn with a display that illuminates the retina through the existing optical system. A key issue is that both channelrhodopsin and halorhodopsin, including their advanced derivatives, require a very high intensity of illumination. Thus, a display system orders of magnitude brighter than normal mobile phone-type displays is required. A number of methods have been proposed including laser scanning, holography, micromirrors, and microLEDs. Perhaps the most promising for efficiency and thus battery life is the latter (Degenaar et al. 2009). In all cases, scalability to hundreds of thousands of stimulation points is possible, significantly more than electronic approaches. In addition to stimulation optoelectronics, an imaging system and image processing system is required. The general processing scheme of the retina is well understood and has been implemented in various forms of hardware over the years. However, with the advent of highly powerful mobile phone technologies, such processing can now be readily integrated with off-the-shelf technology.

For those requiring more invasive brain-level visual prosthesis, the same front-end imaging and imaging processing system can be used, integrated with a pair of glasses. However, rather than having an augmented reality projection unit, information will have to be wirelessly transmitted to a receiver unit which can relay it to the target thalamus or visual cortex. Once there, a special optoelectronic unit will have to transmit light into the target cortical layers using an optrode light delivery system. This would probably look similar to an optical bed of nails. The key challenges as with any brain implant will be to ensure that the system is efficient enough to be able to stimulate the target tissue without causing thermal damage.

Perspectives

Optogenetic forms of retinal prosthesis could present a significant cost-benefit improvement over electronic prostheses, i.e., a large increase in effective vision for a significantly reduced cost

(no implant required). Developing brain-level visual prostheses will be at least as challenging as previous electronic approaches. Furthermore, despite the many advantages of optogenetics, it still requires the introduction of transgenes into human patients. The key question as various groups move toward human trials is whether there are any long-term adverse effects associated with chronic expression of optogenetic proteins. This will be critical to the future of the field.

Artificial retina; Artificial silicon retina (ASR); Electronic retinal implants; Microphotodiode arrays (MPDA); Retina chip; Retinal prosthesis

Definition

Subretinal implants that have been used in clinical trials so far do not use a camera outside the eye for image capturing but a light-sensitive array that is implanted beneath the retina within the layer of lost photoreceptors, utilizing the retinal processing power of the remaining neurons in the inner retina.

Detailed Description

In the human eye, images are captured by natural photoreceptors that are adaptive and highly

sensitive photo-transducers directly connected to a most efficient neuro-processor, the inner retina. Altogether, the inner retina is only $\sim 200\ \mu\text{m}$ thick, optically transparent, and it contains many millions of bipolar, amacrine, and retinal ganglion cells (RGCs). These nerve cells compress visual information in a way that it can be forwarded to the brain via the relatively small number of ganglion cell axons forming the optic nerve. With degenerative loss within the photoreceptor layer, blindness is inevitable although neuronal processing and signal propagation is still functioning in the inner retina.

There exists no cure for blindness caused by hereditary retinal degeneration of the

photoreceptors (e.g., retinitis pigmentosa (RP)), but restoration of vision by various electronic retinal implants has made rapid progress in recent years with remarkable results concerning visual localization of objects, mobility, even reading, and face recognition in some cases. There are, in principle, three different approaches (Fig. 1, from Zrenner 2013): (a) *Epiretinal* implants are positioned on top of the neuroretina, placing electrodes, controlled by a camera outside the body, at the functional *output* of the retina, i.e., near the RGC fibers; (b) *subretinal* implants that (usually) contain light-sensitive photodiodes, each connected to an electrode, are placed beneath the retina, contacting the functional *input* of the retina

Visual Prosthesis, Subretinal Devices,

Fig. 1 The human ascending visual pathway (A) and sites in the retina where epiretinal (B), subretinal (C), and suprachoroidal (D) implants are inserted. (From Zrenner 2013)

on the photoreceptor side; and (c) the *suprachoroidal* approach that inserts electrode arrays from the back of the eye, positioning them on top of the choroid.

Subretinal light-sensitive implants possess several advantages over other types of retinal implants (Zrenner 2002). They provide functional replacement at the retinal input level, substituting for damaged photoreceptors in a retinotopically correct way. Image formation is provided by incident light which reduces the number of external and implanted electronic components. Also, little signal processing is needed because subretinal devices utilize the processing power of the inner retina still present in RP patients after many years of blindness (Santos et al. 1997). Moreover, eye movements can be used to localize objects, and microsaccadic movements of the eye refresh the image which would quickly disappear without such involuntary micro-movements.

The Various Subretinal Implant Developments

The first application of a subretinal implant is by Tassicker (1956), who positioned a selenium photodiode beneath the retina of a blind patient who subsequently reported the sensation of light.

An “artificial silicon retina” (ASR) has been developed since the early 1990s by Chow et al. (cf. Chow’s summary of his studies, 2010) consisting of a 2-mm-diameter microchip that contains approximately 5000 microelectrode-tipped microphotodiodes. The ASR is a passive device without external power, driven solely by the light contained in the image falling onto the retina. The ASR was also applied in clinical trials sponsored by Optobionics (Chicago, IL, USA); it was implanted subretinally in ten RP patients. It was well tolerated and patients were followed up for several years. Improvement and/or slowing of vision loss occurred in six patients, however, not at the site of implantation in retinal periphery but at central retinal areas where some natural photoreceptors had still been functioning. It was hypothesized that the continuous electrical stimulation had induced retinal neurotrophic rescue of

visual acuity, contrast, and color perception in the central retina of these patients. In preclinical studies this group and other groups could indeed show the release of growth factors upon repetitive electrical stimulation, an effect which was confirmed in clinical studies in RP patients (Schatz et al. 2012).

However, the ASR approach – using simple “passive” photodiode arrays powered with natural light – failed, as the small amount of light falling onto a photodiode of a single pixel is not strong enough to restore visual perception point by point in people blind from photoreceptor degeneration. Therefore, one solution, described next, was to use “active” electronic amplification of the photons falling on each pixel of the image receiver.

The *subretinal implant* Alpha-IMS from Retina Implant AG (Reutlingen, Germany) is such an active electronic implant that contains 1500 photodiodes, driving amplifiers and electrodes, spaced 70 μm on a 3×3 mm chip providing the highest pixel density available for patients so far (Fig. 2a). Power and control signals are generated in a small unit that the patient carries and are supplied to the chip by inductivity via a subdermal retroauricular coil from which a subdermal cable leads to the eyeball (Fig. 2b). This type of retinal implant has passed proof of concept in a wire bound pilot study in all patients (Zrenner et al. 2011). A wireless version has been implanted up to now in 40 patients (study ongoing) by a surgical procedure that advances the implant through a window in the sclera transchoroidally into a subretinal channel to the foveal region. In the first, monocentric part of a main study with the Alpha-IMS implant in Tübingen, Germany, Stingl et al. (2013) report restored light perception (8/9 patients), light localization (7/9), motion detection (5/9, angular speed up to 35 deg/s), grating acuity measurement (6/9, up to 3.3 cycles per degree), and visual acuity measurement with Landolt C-rings (2/9) up to Snellen visual acuity of 20/546 (corresponding to a decimal value of 0.037). Identification, localization, and discrimination of objects improved significantly ($p = 0.05$ for each subtest) in repeated tests over a 9-month period. Patients reported numerous beneficial visual experiences in daily life with regained

Visual Prosthesis, Subretinal Devices, Fig. 2 The subretinal implant. (a) The subretinal implant Alpha-IMS device (Retina Implant AG, Reutlingen, Germany) consists of a subretinal chip (#1) containing 1500 light-sensitive photodiodes, amplifiers, and electrodes placed in the region of the retina where photoreceptors have been lost. The brightness of the image projected by the optical lens through the retina onto the chip is analyzed point by point and, after amplification, is forwarded to the bipolar cells of the inner retina. From there, the neuronal network of retinal ganglion cells processes the “electrical image” normally and forwards it to the visual cortex. (b)

The electronic circuits in the chip are powered and controlled by a subdermal receiver behind the ear (#3) that receives power and signals wirelessly through the skin via a transmitter antenna coil (#5) kept in place behind the ear with a subdermal magnet. As seen in the X-ray image, an implanted cable (#7) leads from the subdermal receiver box to the intraorbital space, where it connects to a subretinal foil (#2) with printed gold wires. The battery box (#6) contains electronics that allow the patient to adjust brightness and contrast to the ambient light of the environment. (From Zrenner 2013)

recognition of unknown objects, recognition of facial or clothes characteristics, recognition of moving objects in nature and traffic, improved self-sustaining actions (recognition of doors, door handles), recognition of small objects (glasses, telephone, stapler, washing basin, even dice and numbers of dots on dice), and improved mobility. Control tests were performed each time with the implant’s power source switched off. These data show that subretinal implants can restore visual functions that are useful for daily

life. The Alpha-IMS device has been approved for use in Europe (CE mark) and is under review as an investigational device for US trials. A multi-center trial in Tübingen, Oxford, Hong Kong, London, Dresden, Budapest, and Singapore is underway (see www.clinicaltrials.gov, NCT01024803).

The Boston Retinal Implant (summarized by Rizzo 2011) is not yet in clinical use. It utilizes a hybrid approach where the electrode array is positioned subretinally, but the image-capturing unit is

a camera outside the body, mounted on a spectacles-frame structure that collects visual images. The Boston Retinal Implant Project has focused its efforts on developing scalable technologies to create a hermetic device that can deliver individually controlled pulses of electrical stimulation to each of hundreds of electrodes, but proof of concept in patients has not yet been performed.

The Stanford Retinal Implant comprises a group led by Palanker (Mathieson et al. 2012) and has worked to overcome the difficulties that the passive ASR approach of Chow et al. (2010) has faced. Their subretinal implant which has been tested so far in laboratory situations uses a photovoltaic subretinal array with three serially connected silicon photodiodes in each pixel (70 μm or 140 μm) that receive power and data directly through pulsed infrared illumination; their output current directly stimulates neighboring neurons. With a laboratory-based near-infrared laser (NIR) image projection system, they were able to drive such photodiode arrays *in vitro* in rat retinæ with outer retina degeneration. The application of their approach in humans may still be a number of years away, as biocompatibility with retinal tissue, biostability of the material, and safe surgical procedures have yet to be firmly established. Moreover, the proposed goggles that provide the necessary high brightness images to the subretinal photovoltaic array need to be developed in such a way that they stimulate the subretinal array in a spatially correct manner through the pupil, despite continuing eye movements; it will be a challenge to direct the high-energy radiation of the goggles safely to predetermined retinal locations of a moving blind human eye but it may be possible.

Limitations

Stett et al. (2000) have shown in experiments with multi-electrode arrays in rodent retinæ that the space constant, reflecting the spread of excitation picked up at retinal output neurons, is approximately 50–70 μm . As 280- μm distance between two points on the human retina reflects 1° of visual angle, a maximum resolution of

approximately 12 min of visual angle can be expected, while 1 min can easily be resolved in normal vision. Moreover, images provided by planar electrodes may be able only to provide vision of scenes in various shades of gray, as such electrodes stimulate the red-, blue-, and green-sensitive neurons under each electrode equally; therefore, the chromatic information in visual scenes cannot directly be transmitted in true color.

Summary

Implants positioned in the subretinal space near the fovea can restore useful vision in daily life up to reading of letters and recognition of facial expression for a large group of the approximately 1.5–2 million patients blind from RP worldwide. Only one subretinal implant, the Alpha-IMS (Retina Implant AG, Reutlingen, Germany) is commercially available so far in specialized centers. Development of visual recognition abilities via learning effects and the role of eye movements need to be studied further over the next years.

Visual Prosthesis, Suprachoroidal and Trans-retinal Devices

G. J. Suaning
University of New South Wales, Sydney, NSW,
Australia

Detailed Description

While the number of people with visual impairment is a staggering 285 million (Pascolini and Mariotti 2012), thankfully very few people are profoundly blind, and indeed most people maintain some degree of useful vision. This is particularly true in cases of prevalent degenerative

disorders of the retina such as retinitis pigmentosa (RP) and age-related macular degeneration (AMD) where the typical outcome is legal blindness – defined throughout the developed world typically as being central vision less than 20/200 (6/60 in SI units) or peripheral visual fields constricted to less than 10° or 20° – as opposed to profound blindness. This is further evidenced in that AMD patients make up the majority of blind people in developed nations. Despite the introduction of ranibizumab therapy (Rosenfeld et al. 2006), AMD is still likely to remain the most common cause of legal blindness in developed countries as it addresses the neovascular component of the disease, but there is still no treatment for the atrophic component.

A clinical visual prosthesis is thus most plausibly targeted towards blind people with some remaining visual function such that the prosthesis can work in concert with the visual capacity the implant recipient maintains. In order to interface such a stimulating electrode array with the neural retina while at the same time providing an unobstructed optical pathway, it is desirable to place the array behind the retina as opposed to the interface between the vitreous body and the ganglion cell layer. This approach leaves the subretinal space, a site explored in greatest detail by Stingl et al. (2013), or suprachoroidal and trans-retinal devices – the topic of this entry.

The first suprachoroidal visual prosthesis was initially intended for the subretinal space but was inaccessible during surgery. In 1953, an Australian inventor and radio engineer, Graham Tassicker, patented a retinal stimulator design based upon the Becquerel effect (1839), utilizing the photosensitive material selenium (Tassicker 1956a). This device is the first known visual prosthesis (retinal or otherwise). The first human subject was an “elderly woman,” and the device was implanted at the location between the choroid and sclera owing to the inseparability of the retina from the choroid resulting from the patient’s “advanced condition” of a large central scotoma. Following an apparently event-free recovery, the patient reported seeing “uniform white light” in the region of the implant where a “great dark patch” existed before the operation. The patient

also reported increased confidence in mobility (Tassicker 1956b).

More recently, Korean (Zhou et al. 2008), Australian (Matteucci et al. 2013), and Japanese (Fujikado et al. 2012) researchers have explored the suprachoroidal space as a means of delivering controlled, focal stimuli to the visual system. In the first device to be reported in humans, Japanese researchers have tested two, chronically implanted, 9-electrode devices placed within the sclera. Phosphores were reported to be most effectively elicited using a 20 Hz stimulation frequency.

Further from the neural retina, episcleral devices have also been found to be able to elicit focal responses in the feline (Chowdhury et al. 2008), lending further evidence that trans-retinal devices are feasible for long-term visual prosthesis.

The advantages associated with the placement of suprachoroidal and more distal devices are many. First, the surgical approach is significantly simplified, as there is no need for vitrectomy or any immediate contact with the neural retina. Second, the separation of electrodes from excitable tissue may serve to sequester potentially damaging by-products of electrical stimulation. Third, the placement of stimulating electrode arrays requires no fixation such as retinal tacks and adhesives that can cause trauma or increase the difficulty of removal. Fourth, as mentioned above, the devices do not interfere with remaining vision and may indeed be able to serve as a complimentary therapy to improve mobility to the visually impaired.

The distance from retinal neurons, and the need to balance the charge carrying capacity of stimulating electrodes with the ability to elicit psychophysical perceptions, requires that the management of electric fields (Matteucci et al. 2013) be achieved before suprachoroidal or trans-retinal devices can produce clinically relevant outcomes for the blind.

Voltage Clamp Technique

Thomas Nowotny¹ and Rafael Levi²

¹Centre for Computational Neuroscience and Robotics, School of Engineering and Informatics, University of Sussex, Falmer, Brighton, UK

²The Whitney Laboratory for Marine Bioscience, University of Florida, Augustine, FL, USA

Definition

Voltage clamp is an electrophysiological technique to record electrical currents in biological membranes. It is based on the principle that the current flowing through a cell membrane can be estimated by “clamping” the membrane potential to a constant value using the injection of a mirror current – a current of the same amplitude but reversed polarity.

In practice, the method is used primarily to characterize voltage-dependent conductances in the membrane of neurons by clamping the cells to different stepping potentials. The clamp is achieved with a circuit that quickly detects deviations from the stepping potential and generates currents to correct this deviation. Knowing this current gives the current in the membrane.

Detailed Description

History

The first implementations of voltage clamp go back to Cole (1949) and Hodgkin et al. (1952) and were instrumental in elucidating the mechanism of action potential generation.

In these early implementations, voltage clamp was applied to the giant squid axon using wire electrodes. The clamping amplifier was essentially an operational amplifier that would issue a current proportional to the mismatch of measured membrane potential and command voltage.

Purpose-built amplifiers were designed to eliminate longitudinal (axial) currents so that the action potential occurred only at one locus, a “patch,” and allowed membrane currents in the

patch to be measured as a function of time at any given voltage.

Implementation Details

Modern amplifiers are equipped with a dedicated voltage-clamp mode. It is straightforward to demonstrate (Halliwell et al. 1994) that the voltage clamp is most precise for large amplification factors. However, there is a practical limitation for the amplification factor in that too large amplification can lead to uncontrolled oscillations, essentially caused by overly amplified noise. These oscillations are known as “ringing” and usually result in the destruction of the cell being recorded.

In contrast to the original method, modern methods for voltage clamp (Fig. 1) use glass electrodes instead of wires which allows recording from cells smaller than the giant squid axon. The glass pipettes have very fine tips ($<1\ \mu\text{m}$) which can create difficulties in accurate measurement. First, they are less good conductors than the wires used by Cole and sometimes cannot pass current rapidly enough to compensate for strong cellular currents. This is particularly relevant for fast currents where both the ohmic resistance of the electrode and its capacitive resistance become problematic. A related problem is that current injections cannot control the membrane potential on the entire cell surface for cells where the isopotential condition is not met, at least on fast timescales. This so-called “space clamp” problem was solved in Cole’s device by using a long wire that clamped the squid axon uniformly along its entire length but is acute with glass electrodes.

When using high-impedance glass electrodes, the injected current will create a drop of the electrical potential along the electrode. These electrode artifacts can be considerable, and to allow precise voltage clamp, two separate electrodes are often used for recording and current injection (two-electrode voltage clamp). However, the two-electrode voltage clamp is difficult to use, in particular in smaller mammalian cells, because penetrating neurons with two electrodes is problematic and can cause damage to the cell resulting in leakage of cellular contents and large leakage

Voltage Clamp Technique, Fig. 1 Diagram of a typical voltage-clamp configuration. A cell is impaled by two independent electrodes, one of which is used to monitor the membrane potential and the other to inject currents such that this potential is “clamped” to follow an externally supplied voltage command. The command signal is typically a voltage step from a holding potential to a stepping

potential as shown. The injected current is generated by an operational amplifier or equivalent circuit that compares the observed membrane potential against the command voltage and emits a proportional current. The current is monitored continuously and is the primary source of data in voltage clamp

currents across the membrane. Furthermore, in many preparations, cells are hard to see making it virtually impossible to impale them with a second electrode. To overcome these problems, a number of single-electrode voltage-clamp techniques have been developed.

Single-Electrode Voltage Clamp

Single-electrode voltage clamp allows recording from small cells that would be impossible to impale with two electrodes. There are a number of methods for achieving single-electrode voltage clamp.

Patch Clamp

The ► [“Patch Clamp Technique”](#) allows the study of individual ion channels. It uses an electrode with a larger tip ($>1\ \mu\text{m}$) that has a smooth circular opening. This electrode is pressed against a cell membrane, and suction is applied to the electrode to pull the cell’s membrane until a tight seal with the electrode – preferably more than a gigaohm –

is created. Following the formation of the seal, the membrane is broken by negative pressure, and a continuum is created between the intracellular solution and the electrode inside. Due to the larger diameter of the electrode, the impedance of the electrode is considerably lower, allowing fast, high-current injections with smaller electrode artifacts. Voltage clamp in this configuration has been successfully employed with minimal electrode capacitance and resistance compensation, though other problems such as cytoplasm washout arise.

Discontinuous Single-Electrode Voltage Clamp

In discontinuous single-electrode voltage clamp (SEVC-d), current injection and membrane potential measurement are not performed continuously and simultaneously as in continuous voltage clamp. Instead, the system undergoes a rapid cycle of alternating between passing current and measuring voltage. The amplifier measures voltage in the first few milliseconds of the duty cycle, generates the error signal, and then passes current for the remainder of the cycle to reduce that error.

The method relies on the cell capacitance being significantly larger than the electrode capacitance, typically by at least one order of magnitude, so that electrode artifacts caused by current injection decay until the next membrane potential measurement is obtained, but the membrane potential does not change a lot over the cycle duration. The frequency of the duty cycle must be optimized to match the timescale of the electrode to minimize the remaining artifact when measuring the membrane potential and maximizing the constancy of the membrane potential. The lower the electrode capacitance is, the shorter the cycle can be and the better the voltage control will be.

While discontinuous voltage clamp allows voltage clamp with higher-impedance electrodes, it has limited time resolution and takes more skill than continuous voltage clamp. One of the practical problems often encountered is that the problem of oscillations due to high amplifier gain is much more critical due to the rapid switch between injection and measurement that adds considerable noise.

Current Isolation

The current measured in voltage clamp is a sum of all currents in the cell membrane. To identify individual ionic currents, additional methods for current isolation are necessary, based on some known properties of the currents under investigation. In order to record a single ionic current, one can block other known currents pharmacologically if specific chemical blockers are available.

On rare occasions where the expected voltage sensitivity range of a current of interest is known and is not overlapping with the range of other currents, one can simply limit the test currents to that range. In most other cases, the property of many currents to inactivate at certain membrane

potentials can be used by clever manipulations of the holding voltage and by using so-called pre-steps to selectively inactivate currents. Pre-stepping the holding potential to a level that inactivates currents other than the current under investigation practically blocks them. Finally, currents can be manipulated by altering external ion composition, creating an environment that would not be conducive for certain currents.

Data Analysis and Modern Developments

Traditionally, voltage-clamp data is analyzed by measuring the steady-state activation of a current toward the end of the voltage step, and the slope of the current rises in the early part of the response to inform Hodgkin-Huxley-type phenomenological models of the ionic currents in the cell membrane. An example of a minimal set of a Na and K current to describe a hippocampal cell is shown in Table 1. With the advent of faster computers, the traditional analysis methods have been replaced by more precise parameter estimation methods on the full trace of the current response (Willms et al. 1999; Willms 2002). Some recent extensions have continued this trend by introducing novel clamping potential waveforms (Gurkiewicz and Korngreen 2007; Drix and Nowotny 2011) as the full trace method does not require constant voltage steps.

A different modern development has been active electrode compensation (Brette et al. 2008; Samu et al. 2012) where instead of using discontinuous current injections in single-electrode voltage clamp, a computer is used to estimate the voltage artifacts on a single electrode in real time and digitally subtracts them from the

Voltage Clamp Technique, Table 1 A typical Hodgkin-Huxley model of a hippocampal cell (Traub and Miles 1991)

$C \frac{dV}{dt} - I_{Na} - I_{Kd} - g_{leak}(V - V_{leak}) + I_{ext}$	V membrane potential, C capacitance, g_{leak} , V_{leak} leak current, I_{ext} externally applied current
$I_{Na} = g_{Na} m h^3 (V - V_{Na})$, $I_{Kd} = g_{Kd} n^4 (V - V_{Nd})$	g_{Na} , g_{Kd} maximal conductances
$\frac{dx}{dt} = a_x(1 - x) - \beta_x x$	$x = m, n$ activation variables, $x = h$ inactivation variable
$\alpha_x = \sigma_{\alpha x}(V)$, $\beta_x = \sigma_{\beta x}(V)$	$\sigma_{\cdot x}$ denote sigmoid function with three parameters for each $x = m, h, n$

measured membrane potential. This new method allows continuous single-electrode voltage clamp with relatively high-impedance electrodes.

Definition

Voltage-sensitive dye imaging is an experimental technique to measure neuronal network activity from *in vivo* brains or live brain slices. In this technique, exogenous chemical agents are employed to continuously and rapidly transduce changes in cell membrane potential into changes in fluorescence emission.

Intrinsic optical imaging uses light at various wavelengths to probe activity-induced changes in the intrinsic optical properties of the brain tissues. The most common changes measured by intrinsic optical imaging are hemoglobin oxygenation and concentration because hemoglobin is a major chromophore in brain tissues within the visible wavelength region.

Detailed Description

Voltage-sensitive dye imaging (VSDI) and intrinsic optical imaging (IOI) are both spatiotemporal neuroimaging methods. However, measurements from VSDI are direct reflections of changes in neural electrical activity, whereas measurements from IOI are related to changes in hemoglobin concentration and hemoglobin oxygenation.

Voltage-Sensitive Dyes

Voltage-sensitive dyes (VSDs) are chemical agents which, when embedded to a cell membrane, change their fluorescence properties in response to changes in the cell membrane potential. The earliest VSDs (such as merocyanines) were photosensitizing agents obtained from commercial suppliers such as Kodak™ and BASF™ and were originally designed to be used in photochemical processes in the photographic industry. While modern VSDs such as di-4-ANEPPS (a styryl dye from Invitrogen) and RH1691 (an oxonol dye synthesized by Rina Hildesheim at Optical Imaging Ltd.) are now synthesized specifically for use in research applications, it took the screening of hundreds of commercially available photosensitizing agents and their analogues before the chemical groups necessary for a successful fluorescence dye were identified. Within the chemical structure of a VSD, a hydrophobic group is required to anchor the VSD directly to the lipid-rich cell membrane. This allows VSD to be aligned perpendicularly to the membrane surface and hence reliably transduce the weak transmembrane potential.

The concept of using molecular transducers to optically indicate electrical activity was first proposed in the 1950s, but it took more than 10 years to successfully realize it in cell cultures (Tasaki et al. 1968) and invertebrate ganglia (Salzberg et al. 1973). These early studies were crucial in recognizing the importance of signal-to-noise ratios of VSDs and identifying undesirable properties of VSDs that should be removed or at least reduced in order to use VSDI to reliably record the neuronal network activity from either the *in vivo*

brains or the *in vitro* brain slices. The first of such properties is direct pharmacological side effects of VSDs that can change ionic conductances and therefore disrupt basic properties of electrical cellular activity. The second undesirable property is that the interaction of the dye molecule with light can provide further damage to the tissue by the formation of highly toxic free radicals, a property of a VSD known as phototoxicity. Finally, the overall fluorescence signal received from the stained tissue may decrease over time because of the irreversible photobleaching of VSDs.

Voltage-Sensitive Dye Imaging

The intensity of the VSDI signal is linearly correlated with the changes in the magnitude of the membrane potential and the area of membrane elements stained. The initial VSDI studies – which used relatively simple cell cultures in conjunction with intracellular electrophysiological recordings – demonstrated the similarity between the signals at the electrode tip produced by VSDI and the intracellular electrode (Cohen et al. 1974). Thus, VSDI has the potential to generate real-time data that is comparable to signals obtained from two-dimensional arrays of electrophysiological recording electrodes.

Although some modern VSDs still exhibit some unwanted side effects (e.g., Grandy et al. 2012), the overall improvement in VSDI over the past decades has allowed this technique to be used successfully in a range of applications involving *in vivo* brains and *in vitro* brain slices which in turn provides a greater understanding of the network properties of many cortical processing systems. For example, VSDI was used to visualize the interactions between incoming sensory information and ongoing activity on the surface of the brains of awake, behaving rodents (Ferezou et al. 2006). VSDI was also used to study *in vivo* and *in vitro* brain tissues to reveal how the horizontal connections among neighboring cortical regions and the vertical connections between different cortical layers uniquely influence cortical function (Reynaud et al. 2012; Sato et al. 2008; Tucker and Katz 2003; Wester and Contreras 2012). The same

technique was used to visualize the communication between the visual cortical and the subcortical structures, such as the thalamus (MacLean et al. 2006). Finally, the combination of VSDI and the computational models of cortical functions has begun to shed light on the fundamental means by which the cortex encodes the rich complexity of incoming sensory information (Zhou et al. 2013).

Limitations of VSDI

Despite the excellent spatial resolution (in tenths of micrometers maximum) and temporal resolution (in the millisecond range), the depth of the investigation of VSDI is greatly limited by the high scattering properties of biological tissue. Therefore, VSDI can only be used to study superficial structures, such as cerebral cortex, and brain slices.

Intrinsic Optical Imaging

IOI is used mainly for two purposes: to map focal activation in the cerebral cortex, such as pinwheel and ocular dominance structures in the visual cortex, and to investigate mechanisms of neurovascular coupling by measuring the changes in cerebral hemodynamics induced by neural activities. In general, the contrast in IOI is originated from the changes in hemoglobin concentration and oxygenation within the tissue volume imaged. The technique can be performed with either a single-wavelength or a multiple-wavelength illumination light depending on the research question being asked.

Single-Wavelength IOI

It is generally used for, for example, pinwheel structures, ocular dominance, or retinotopic mapping in the cortex (Frostig et al. 1990; Grinvald et al. 1991). The choice of the illumination light wavelength determines the aspect of the intrinsic response monitored. If the wavelength is an

isosbestic point in the oxyhemoglobin and deoxyhemoglobin absorption spectra, the changes in the diffusely reflected light will mostly reveal the changes in regional hemoglobin concentration or blood volume. This type of measurement by IOI tends to be more robust. Other wavelengths can also be used to investigate the changes in hemoglobin saturation. To generate a spatial map of activation from the images of IOI, sophisticated image processing is often required to remove so-called “global” components of the response, common to each stimulation type, to reveal the “mapping” components.

Multiwavelength IOI

It is often referred to as optical imaging spectroscopy (OIS) or 2-dimensional optical imaging spectroscopy (2D-OIS). In an OIS system, the cortex is illuminated by a broadband light source and the reflected light from the area of investigation is dispersed by a diffraction grating and recorded (Malonek and Grinvald 1996). In a 2D-OIS system, the cortex is illuminated by a specific number of wavelengths of light selected through a filter wheel, LED, or galvanometer-based system (Berwick et al. 2008; Devor et al. 2008). By measuring the reflected light at multiple wavelengths and then comparing their intensity with the absorption spectra of oxy- and deoxyhemoglobin, the changes in the concentration of these two chromophores in the brain tissue can be estimated. This technique has led to many advances in the understanding of neurovascular coupling, a mechanism by which the brain controls its blood supply.

Limitations of IOI

IOI is an invasive brain imaging technique because light used to illuminate the cortex is generally within the visible wavelength range (450–630 nm) and does not penetrate through the skull due to scattering. Therefore, the majority of the research involving IOI is carried out on the rodent preparation with the skull either removed

or thinned to translucency. Further surgery to remove the dura is needed for experiments on primate and feline animal models.

Wavelet Analysis

Hualou Liang
School of Biomedical Engineering,
Drexel University, Philadelphia, PA, USA

Definition

Wavelet analysis is a powerful signal processing method that represents a signal in terms of wavelets. A wavelet or small wave is a wavelike function, upon scaled and translated, that can be used to decompose a signal into its basic constituent components at different scales. Each scale component can be converted into a frequency range. The resulting wavelet transform measures the time-frequency variations of frequency components in a nonstationary signal. Wavelet analysis is thus a natural choice for the analysis of neural data in which the nonstationarity is abundant.

Detailed Description

Techniques for wavelet analysis generally consist of continuous and discrete wavelet transforms that are below described and related to each other. Wavelet analysis is then contrasted with Fourier analysis, followed by its applications in neural data analysis.

Continuous and Discrete Wavelet Transforms

Continuous wavelet transform (CWT) is used to decompose a continuous time signal into scaled and translated wavelets, which is defined as (Daubechies 1992; Mallat 1998)

$$w(a, b) = \frac{1}{\sqrt{a}} \int_{-\infty}^{\infty} x(t) \psi^* \left(\frac{t-b}{a} \right) dt$$

where a is the scale parameter, b is the translation parameter, and $\psi(t)$ is the wavelet basis function or mother wavelet, with $*$ representing the complex conjugate. For example, the commonly used Morlet wavelet, $\psi(t) = \exp(i\omega_0 t) \exp(-t^2/2)$, which is just a complex sine wave modulated by a Gaussian envelope. ω_0 is the wavenumber, specifying the number of the cycles of each wave that the wavelet measures. Although time and frequency do not appear explicitly in the transform, the scale and translation parameters, respectively, provide the frequency range and the time location of an event. Whereas dilated versions of $\psi(t)$ match low-frequency components, contracted versions match high-frequency oscillations. Hence, the CWT exhibits the property of “zooming” in on the sharp temporal variations in a signal. The scalogram of a signal, wavelet analogy of the spectrogram,

is generated by varying parameters in the scale dilation and translation, giving rise to multiresolution analysis.

The CWT still uses discretely sampled data; however, the translating operator smoothly varies along the data sample, and the scaling operator allows much finer encoding resolution as it is defined on a frequency range. This improved resolution of the CWT comes at the expense of increase in time, memory, and computational complexity required to calculate the continuous wavelet coefficients. The discrete wavelet transform (DWT), on the other hand, is not merely a discretized CWT. Instead, the scale and translation parameters are discretized, and for fast numerical implementation, the scale normally varies along a dyadic sequence (the scaling and translation operators are based on powers of 2).

Comparisons with Fourier Analysis

Wavelet analysis is similar to Fourier analysis in that it splits a signal down into its basic constituent components. Whereas the Fourier transform represents the signal as a series of sine waves of different frequencies, the wavelet transform represents signals as linear combinations of wavelets. In comparison to Fourier analysis, it becomes clear that (1) the basis functions in the WT are not limited to the sinusoidal waves, but rather are chosen by the user; and (2) wavelets are localized in both time and frequency, but the Fourier transform is only localized in frequency. In terms of time-frequency localization, the WT is more similar to the short-time Fourier transform (STFT). The main difference is that the STFT uses a single analysis window width, whereas the WT principally uses short windows at high frequencies and longer windows at low frequencies. Nonetheless, both the STFT and wavelet analysis are limited by the fundamental uncertainty principle, in which both time and frequency cannot simultaneously be resolved with the same precision.

Applications in the Analysis of Neural Data

The WT has emerged as a powerful tool for analyzing signals of a nonstationary nature. Applications of wavelet transform to the analysis of neural data mainly include efficient signal representation, signal estimation, and signal compression. Most of its applications have been in time-frequency spectral representation of neurophysiologic data such as EEG (e.g., Tallon-Baudry et al. 1996; Blanco et al. 1998), where the WT is employed for the detection and extraction of significant events of varying frequencies, such as localized rhythmical changes or transient events. Since wavelet transform was used for evoked potential analysis of EEG in the 1990s (Bartnik et al. 1992; Bertrand et al. 1994; Quian Quiroga and Schürmann 1999), single-trial evoked potential estimation using wavelets has attracted growing attention (Quian Quiroga and Garcia 2003; Wang et al. 2007, 2009). In the analysis of spike train data, the WT has been used for signal denoising, feature extraction and decoding, and spike sorting and detection (Hulata et al. 2000; Letelier and Weber 2000; Laubach 2004; Quian Quiroga et al. 2004; Nenadic and Burdick 2005).

The advantage of wavelet analysis lies in its resolution flexibility attributable to a set of wavelets which make the WT suitable for the description of nonperiodic and nonstationary processes, even in the presence of discontinuities and sharp peaks. In practice, the analysis results depend on the choice of basis wavelet function, which is arbitrary and may not be well adapted to represent the signals. The problem is therefore how to select an appropriate basis, among a large set of different wavelets, for analyzing a particular class of signals. An alternative is to use data-driven empirical mode decomposition method, which seems to be promising in the analysis of cortical field potential data (Liang et al. 2005a, b).

Weak Coupling Theory

Timothy J. Lewis¹ and Michael A. Schwemmer²

¹Department of Mathematics, University of California, Davis, CA, USA

²Mathematical Biosciences Institute, The Ohio State University, Columbus, OH, USA

Detailed Description

The theory of weak coupling (Kuramoto 1984; Kopell and Ermentrout 2002; Brown et al. 2004; Izhikevich 2007; Schwemmer and Lewis 2012) has been extremely helpful in developing our understanding of synchronization in neuronal networks. The theory allows one to reduce the dynamics of a weakly coupled network of neuronal oscillators to a system of equations involving only the phase of each oscillator. The resulting “phase models” are given in terms of the neurons’ infinitesimal phase response curves (iPRCs) and the input to the neuron via coupling. This article provides an explanation of how the phase models are derived and gives an example of how the theory can be used to determine phase-locking in a pair of neurons connected by reciprocal inhibition.

Model Neuronal Networks and Phase Models

A network of M weakly coupled heterogeneous neurons can be represented by

$$\frac{dX_j}{dt} = F(X_j) + \varepsilon \tilde{F}_j(X_j) + \sum_{k=1}^M \varepsilon \sigma_{kj} I(X_j, X_k),$$

$$j = 1, \dots, M$$
(1)

where X_j is an N -dimensional vector, containing the state variables of the neuron j (e.g., membrane potential(s), gating variables for ionic membrane conductances, ion concentrations, and perhaps

variables describing the output of chemical synapses). $F(X_j) + \varepsilon \tilde{F}_j(X_j)$ is a vector function describing the state-dependent rates of change of the state variables of the isolated neurons in time; $\varepsilon \tilde{F}_j(X_j)$ accounts for heterogeneity between cells. The term $\varepsilon \sigma_{kj} I(X_j, X_k)$ describes the influence of neuron k on neuron j , where σ_{kj} is the relative coupling strength. ε is a small parameter that scales the magnitude of the heterogeneity and the coupling, ensuring that both are “weak.” All neurons in the network are assumed to be intrinsic oscillators. Specifically, in the unperturbed case ($\varepsilon = 0$), all neurons exhibit stable T -periodic firing. This corresponds to an asymptotically stable T -periodic limit cycle solution for the system $\frac{dX_j}{dt} = F(X_j)$. We will denote this limit cycle solution as the N -dimensional T -periodic vector function $X_{LC}(t + \phi)$, where ϕ is an arbitrary phase shift.

Because the neurons are weakly coupled, the neurons’ intrinsic dynamics are dominant, and the system remains close to the limit cycle. However, small phase shifts due to the coupling can accumulate systematically and eventually, lead to phase-locked states, i.e., fixed relationships between the phases of the neurons. The theory of weakly coupled oscillators reduces the dynamics of the neuronal network to a “phase model” that captures these effects of coupling on the phases of the neurons.

In the phase model for the network, the state of each neuronal oscillator is completely described by its phase θ_j , and the evolution of θ_j is given by

$$\frac{d\theta_j}{dt} = 1 + \varepsilon \omega_j + \varepsilon \sum_{k=1}^M \sigma_{jk} H(\theta_j - \theta_k), \quad (2)$$

$j = 1, \dots, M.$

The function H , which is called the *interaction function*, is determined by

$$\varepsilon H(\theta_j - \theta_k) = \frac{1}{T} \int_0^T Z(\tilde{t}) \cdot (\varepsilon I(X_{LC}(\tilde{t}), X_{LC}(\tilde{t} + (\theta_j - \theta_k)))) d\tilde{t}. \quad (3)$$

The frequency of the unperturbed neuronal oscillators is taken into account by the 1 on the

right-hand side of Eq. 2. The term $\varepsilon \omega_j$ accounts for the small deviations away from this frequency due to heterogeneity and is given by

$$\varepsilon \omega_j = \frac{1}{T} \int_0^T Z(\tilde{t}) \cdot (\varepsilon \tilde{F}_j(X_{LC}(\tilde{t}))) d\tilde{t}. \quad (4)$$

The function $Z(t)$ in the interaction function (Eq. 3) and the heterogeneity term (Eq. 4) is the *infinitesimal phase response curve* (iPRC), which characterizes the phase shift of the neuronal oscillator to a small abrupt (delta-function-like) perturbation.

Note that the theory of weakly coupled oscillators reduces the dimension of the system from the original NM to M , and the system can be further reduced to $M - 1$ when the phase difference between the neurons is considered. For example, a pair of neurons described by the four-variable Hodgkin-Huxley model (Hodgkin and Huxley 1952) augmented by a one-variable chemical synapse can be reduced from a ten-dimensional system to a one-dimensional system. The reduction method can also be readily applied to more complex models, including multicompartment model neurons and network oscillators (e.g., Zahid and Skinner 2009; Zhang and Lewis 2013), which can render a significantly larger dimension reduction. In fact, the method has been applied to real neurons as well (e.g., Mancilla et al. 2007).

The reduction to the phase model makes several approximations that require the coupling between neurons and heterogeneity of the neurons to be sufficiently weak. “Sufficiently weak” implies that the effects of the coupling and heterogeneity account for only a small fraction of the instantaneous frequency of each neuronal oscillator ($d\theta_j/dt$) at each point in the cycle. That is, for the phase model to quantitatively capture the dynamics of the original network (Eq. 2), the influence of heterogeneity and coupling $|\varepsilon \tilde{F}_j(X_j) + \sum_{k=1}^M \varepsilon \sigma_{kj} I(X_j, X_k)|$ should be an order of magnitude smaller than the effects of the intrinsic dynamics of the neurons $|F(X_j(t))|$. However, it is important to point out that phase models often capture the qualitative behavior of systems for moderate levels of heterogeneity and coupling strengths (Lewis and Rinzel 2003; Netoff et al. 2005).

In the following section, we further describe the components of phase models and provide a derivation of phase models. We then show how the theory can be used to analyze phase-locking dynamics in a pair of reciprocally connected Morris-Lecar neurons. Note that more extensive descriptions of the theory of weakly coupled oscillators can be found in Schwemmer and Lewis (2012), as well as many other reviews.

Derivation of Phase Models

There are several methods of deriving phase models, and each method has its own benefit. A geometric approach, which was originally introduced by Kuramoto (1984), gives a beautiful geometric interpretation of the iPRC and deepens the understanding of the mechanisms underlying the phase response properties of neurons. A systematic singular perturbation approach, which was developed independently by Malkin (1956), Neu (1979), and Ermentrout (1981), provides an efficient method for computing iPRCs for model neurons. The reduction method presented here is in the spirit of Winfree's early work with phase models (Winfree 1980) and regards the iPRC as an impulse response function for oscillatory systems. While it is least rigorous, it is probably the most intuitive approach, and it clearly highlights the key idea of the theory of weakly coupled oscillators, which is that neurons behave linearly in response to small perturbations and therefore obey the principle of superposition. Furthermore, this method most closely relates the iPRC to PRCs that can be experimentally measured. Schwemmer and Lewis (2012) describe all three methods and show how they relate to one another.

The Phase of Oscillators

The phase of a neuronal oscillator is a measure of the time that has elapsed as the neuron moves through its periodic cycle, starting from an arbitrary reference point in the cycle. We define the phase of an unperturbed periodically firing neuron j at time t to be

$$\theta_j(t) = (t + \phi_j) \bmod T, \quad (5)$$

with $\theta_j = 0$ set to be at the peak of the neurons' spike (Fig. 1). (Phase is often normalized by the period T or by $T/2\pi$, so that $0 \leq \theta_j < 1$ or $0 \leq \theta_j < 2\pi$, respectively. Here, we do not normalize phase and take $0 \leq \theta_j < T$.) The constant ϕ_j , which is referred to as the *relative phase* of the j th neuron, is determined by the position of the neuron on the limit cycle at time $t = 0$. Thus, for the unperturbed neuron, $\frac{d\theta_j}{dt} = 1$ (as indicated in the phase model equation (2) with $\varepsilon = 0$). Note that each phase corresponds to a unique position on the neuron's T -periodic limit cycle, and any solution of the unperturbed neuron that is on the limit cycle can be expressed as

$$X_j(t) = X_{LC}(\theta_j(t)) = X_{LC}(t + \phi_j). \quad (6)$$

Weak Coupling Theory, Fig. 1 Phase in an oscillating Morris-Lecar model augmented by an output synapse (see section “Derivation of Phase Models”). From top to bottom Membrane potential V , gating variable n , synaptic variable S and phase $\theta(t)$ during T -periodic firing. The phase, $\theta(t)$, increases linearly from 0 to T . Zero phase is assumed to occur at the peak of the voltage spike

When a neuron is subjected to perturbations, the exact correspondence of time to phase (Eq. 5) is no longer valid. However, when the perturbations are weak, the neuron remains close to the asymptotically stable limit cycle, and the only significant effects of the perturbations are to adjust the relative phase of the neuron by slightly accelerating or decelerating the progression around the limit cycle. Therefore, the state of neuron j can be well approximated by $X_j(t) \simeq X_{LC}(t + \phi_j(t))$, where the relative phase ϕ_j is now a function of time t . The goal now is to understand how the relative phase of the neuron $\phi_j(t)$ is affected by perturbations due to heterogeneity, coupling to other neurons, and any other input to the oscillating neuron.

The Infinitesimal Phase Response Curve

Before considering how perturbations in general affect the relative phase of an oscillating neuron, first consider the response of a neuron to a small abrupt perturbation. Specifically, suppose that a small brief square current pulse of amplitude εI_0 and duration Δt is delivered to a neuron when it is at phase θ^* . This small, brief current pulse causes the membrane potential to abruptly increase by $\Delta V \simeq \varepsilon I_0 \Delta t / C$, i.e., the change in voltage will approximately equal the total charge delivered to the cell by the stimulus, $\varepsilon I_0 \Delta t$, divided by the capacitance of the neuron, C . The perturbation can cause the cell to fire sooner (phase advance) or later (phase delay) than it would have fired without the perturbation. The magnitude and sign of this *phase shift* depends on the amplitude and duration of the stimulus, as well as the phase in the oscillation at which the stimulus was delivered. This relationship is quantified by the phase response curve (PRC), which gives the phase shift $\Delta\phi$ as a function of the phase θ^* for a fixed $\varepsilon I_0 \Delta t$ (Fig. 2).

For sufficiently small and brief stimuli, the neuron will respond in a linear fashion, and the PRC will be proportional to the magnitude of the current stimulus:

$$\begin{aligned} \Delta\phi(\theta^*) &\simeq Z_V(\theta^*) \\ \Delta V &= Z_V(\theta^*) \left(\frac{1}{C} \varepsilon I_0 \Delta t \right), 0 \leq \theta^* < T, \end{aligned} \quad (7)$$

where $Z_V(\theta^*)$ describes the proportional phase shift as a function of the phase of the stimulus. The function $Z_V(\theta)$, which is known as the infinitesimal phase response curve (iPRC) or the phase-dependent sensitivity function for voltage perturbations, quantifies the normalized phase shift due to an infinitesimally small δ -function-like voltage perturbation delivered at any given phase on the limit cycle. Note that Eq. 7 implies that

$$Z_V(\theta^*) = \frac{\partial \theta}{\partial V}(\theta^*)$$

In principle, any state variable of a neuronal oscillator can be perturbed (e.g., the different voltage variables in a multi-compartmental model, any gating variables or ionic concentrations, as well as firing rate variables in Wilson-Cowan-type models), and therefore, an iPRC for any variable can be measured. Indeed, the iPRC for a neuronal oscillator can be generalized to be a vector function $Z(t)$ in which each component describes the iPRC corresponding to a particular state variable. For example, a Morris-Lecar model augmented by an output synapse (see section on “Derivation of Phase Models” and Fig. 1) has state variables $X = [V, n, S]^T$ and the iPRC is the vector $Z(t) = [Z_V(t), Z_n(t), Z_S(t)]^T$, as shown in Fig. 2.

Phase Models for Weakly Forced Neurons

Now, consider the response of neuron j to weak input $\varepsilon P_j(t)$ in general:

$$\frac{dX_j}{dt} = F(X_j) + \varepsilon P_j(t). \quad (8)$$

Note that $\varepsilon P_j(t)$ is an N -dimensional vector function containing perturbation in any or all state variables. As mentioned earlier, because

Weak Coupling Theory,

Fig. 2 iPRCs for an oscillating Morris-Lecar neuron augmented by an output synapse (see section “Derivation of Phase Models” and Fig. 1). The voltage $V(t)$ and gating variable $n(t)$ components of limit cycle oscillations are plotted along with their corresponding iPRCs. The iPRCs are measured by (i) delivering a small brief perturbation to the variable at phase θ^* and measuring the subsequent change in period $\Delta\theta$ and then (ii) plotting the change of phase normalized by the magnitude of the stimulus as a function of θ^* . The iPRC for a synaptic output variable S (not shown) is zero for input at all phases. Because it is strictly an output variable, perturbations to it will not affect the oscillations of the neuron directly

the input is weak, the neurons' intrinsic dynamics dominate the dynamics of the system, and $X_j(t) \simeq X_{LC}(\theta_j(t)) = X_{LC}(t + \phi_j(t))$. This assumes that the input affects the speed at which cells move around the neuron's limit cycle but it does not affect the amplitude of the oscillations. Thus, the effects of the weak input are entirely captured in the dynamics of the relative phases of the cells $\phi_j(t)$. The assumption of weak input also ensures that the perturbations to the neuron are sufficiently small so that the neuron responds linearly to the input. This implies that (i) the small phase shifts of the neuron due to the presence of the input for a brief time Δt can be

approximated using the iPRC (Eq. 7) and (ii) these small phase shifts in response to the input sum linearly (i.e., the principle of superposition holds). That is, (i) the iPRC can be used to determine the phase shift due to the input from t_i to $t_i + \Delta t$

$$\begin{aligned} \Delta\phi_j(t_i) &= \phi_j(t_i + \Delta t) - \phi_j(t_i) \\ &= Z(\theta_j(t_i)) \cdot (\varepsilon P_j(t_i)) \Delta t. \\ &= Z(t + \phi_j(t_i)) \cdot (\varepsilon P_j(t_i)) \Delta t, \end{aligned}$$

and (ii) the accumulated phase shifts due to the input $\varepsilon P_j(t)$ from 0 to $t = m\Delta t$ are

$$\phi_j(t) - \phi_j(0) = \sum_{i=1}^m Z(t + \phi_j(t_i)) \cdot (\varepsilon P_j(t_i)) \Delta t.$$

Taking the limit as $\Delta t \rightarrow 0$, we obtain an integral equation for the evolution of the relative phase of neuron j :

$$\phi_j(t) - \phi_j(0) = \int_{t=0}^t Z(\tilde{t} + \phi_j(\tilde{t})) \cdot (\varepsilon P_j(\tilde{t})) d\tilde{t}. \quad (9)$$

Note that this integral equation has a form similar to a convolution of the iPRC and the input, which indicates that the iPRC is analogous to an impulse response function or Green's function for an oscillating system.

The standard form of a phase model, which governs the evolution of the relative phase of a neuron subjected to weak input, can be obtained by putting the integral equation (9) in its differential equation form:

$$\frac{d\phi_j}{dt} = Z(t + \phi_j) \cdot (\varepsilon P_j(t)). \quad (10)$$

Note: The Link Between the iPRC and General PRCs

The iPRC measures the normalized phase shift in response to small abrupt stimuli. If the neuron is being stimulated with a general small amplitude time-dependent input $\varepsilon I_0(t)$ rather than an abrupt pulse, we can take advantage of the property of superposition and see that the PRC for general

small amplitude stimuli can be estimated from the iPRC by

$$PRC(\phi) = \int_0^\infty Z(t) \cdot (\varepsilon I_0(t - \phi)) dt. \quad (11)$$

Note that as the amplitude of the perturbation increases, the assumption of linearity (superposition) breaks down and the PRC is not necessarily well approximated by a scaled version of the iPRC.

Phase Model for Networks of Coupled Neurons

The input $\varepsilon P_j(t)$ to neuron j described in the previous subsection could be due to an externally applied stimulus, but it could also be due to weak coupling to other neurons in the network or weak heterogeneity. It could also arise from a combination of these perturbations, which is the case for the network of M weakly coupled neurons with weak heterogeneities in the intrinsic properties, described in Eq. 1, i.e.,

$$\begin{aligned} \varepsilon P_j(t) &= \varepsilon \tilde{F}_j(X_j(t)) + \sum_{k=1}^M \varepsilon \sigma_{kj} I(X_j(t), X_k(t)) \\ &= \varepsilon \tilde{F}_j(X_{LC}(t + \phi_j(t))) \\ &\quad + \sum_{k=1}^M \varepsilon \sigma_{kj} I(X_{LC}(t + \phi_j(t)), X_{LC}(t + \phi_k(t))). \end{aligned}$$

Thus, the phase model for this network is

$$\frac{d\phi_j}{dt} = Z(t + \phi_j(t)) \cdot \left(\varepsilon \tilde{F}_j(X_j) + \sum_{k=1}^M \varepsilon \sigma_{kj} I(X_{LC}(t + \phi_j(t)), X_{LC}(t + \phi_k(t))) \right). \quad (12)$$

Note that the limit cycle solution $X_{LC}(t)$ and the iPRC $Z_\nu(t)$ are T -periodic functions and the scaling of the right-hand side of Eq. 12 by the small parameter ε indicates that changes in the relative

phases ϕ_j occur on a much slower timescale than the period of oscillation T . Therefore, we can integrate the right-hand side over the full period T holding the values of ϕ_j constant to find the

average rate of change of the ϕ_j over a cycle. This eliminates the explicit time dependence on the right-hand side of phase equation (12) to obtain

autonomous system of differential equations that approximate the slow-time evolution of the relative phases ϕ_j :

$$\begin{aligned} \frac{d\phi_j}{dt} = & \frac{1}{T} \int_0^T Z(\tilde{t} + \phi_j) \cdot \left(\varepsilon \tilde{F}_j(X_{LC}(\tilde{t} + \phi_j)) + \right. \\ & \left. \sum_{k=1}^M \varepsilon \sigma_k = \varepsilon \frac{1}{T} \int_0^T Z(\tilde{t}) \cdot \tilde{F}_j(X_{LC}(\tilde{t})) d\tilde{t} + \right. \\ & \left. \varepsilon \sum_{k=1}^M \sigma_{kj} \frac{1}{T} \int_0^T Z(\tilde{t}) \cdot \left(I(X_{LC}(\tilde{t}), X_{LC}(\tilde{t} + (\phi_j - \phi_k))) \right) d\tilde{t} \right) = \varepsilon \omega_j + \varepsilon \sum_{k=1}^M \sigma_{kj} H(-(\phi_j - \phi_k)). \end{aligned} \quad (13)$$

Note that the relative phases ϕ_j are assumed to be constant with respect to the integral over T in $\tilde{t}$, but they vary in t . (This averaging process is made rigorous by averaging theory (Guckenheimer and Holmes 1983; Ermentrout and Kopell 1991).) The phase model presented in Eq. 2, which is written in terms of the actual phase of the neuronal oscillator, is obtain from the phase model Eq. 13, which is in terms of relative phase, by using the definition $\theta_j(t) = t + \phi_j(t)$. Both equations show that (i) the effects of weak heterogeneity in the intrinsic properties of the neurons in the network are captured by a constant shift in the intrinsic frequency of each neuron $\varepsilon \omega_j$ and (ii) the effects of the coupling between any pair of neurons are captured by the interaction function H , which is a

function of the phase difference between the two cells.

Example: Phase Model for a Pair of Morris-Lecar Neurons Coupled by Reciprocal Inhibition

As a concrete application of the theory of weakly coupled oscillators, consider a pair of the Morris-Lecar neurons with heterogeneity in their leakage conductances and coupled by inhibitory synapses (as described in Fig. 1). That is, (i) the intrinsic dynamics of the neurons are given by the Morris-Lecar (ML) model (Morris and Lecar 1981) with $X_j = [V_j, n_j, S_j]^T$ and

$$F(X_j) = \begin{bmatrix} \frac{1}{C} (-g_{Na} m_\infty(V_j)(V_j - E_{Na}) - g_K n_j(V_j - E_K) - g_L(V_j - E_L) + I) \\ \frac{n_\infty(V_j) - n_j}{\tau_n(V_j)} \\ \frac{S_\infty(V_j) - S_j}{\tau_S(V_j)} \end{bmatrix},$$

where the standard ML system has been augmented with the variable S_j that describes the dynamics of the synaptic output of the neuron; (ii) the heterogeneity between cells is

$$\varepsilon \tilde{F}(X_j) = \begin{bmatrix} \frac{1}{C} (\tilde{g}_{Lj}(V_j - E_L)) \\ 0 \\ 0 \end{bmatrix},$$

Weak Coupling Theory, Fig. 3 G -function for two Morris-Lecar neurons coupled by reciprocal inhibition. The G -function $G(\phi)$ is plotted as a thick line. $G(\phi^*) = -\Delta\omega$ indicate phase-locked states at ϕ^* . Phase-locked state for various levels of heterogeneity ($\Delta\omega$). Phase-locked states at which $G'(\phi^*) < 0$ are stable (filled circles), and phase-locked states at which $G'(\phi^*) > 0$ are unstable (open circles)

where $\tilde{g}_{Lj}$ is the difference between the leakage conductance of neuron j and the mean leakage conductance of the population g_L ; and (iii) the coupling is modeled by conductance-based synapses (e.g., Proctor and Holmes 2010) with a homogeneous coupling strength ($\sigma_{jk} = 1$),

$$\varepsilon I(X_j, X_k) = \begin{bmatrix} \frac{1}{C} \left(g_{syn} S_k (V_j - E_{syn}) \right) \\ 0 \\ 0 \end{bmatrix}.$$

Following the derivation in the previous section, one can obtain the phase model that governs the slow evolution of the relative phases of the two coupled neurons:

$$\begin{aligned} \frac{d\phi_1}{dt} &= \varepsilon\omega_1 + \varepsilon H(\phi_2 - \phi_1) \\ \frac{d\phi_2}{dt} &= \varepsilon\omega_2 + \varepsilon H(-(\phi_2 - \phi_1)), \end{aligned} \quad (14)$$

where

$$\varepsilon H(-\phi) = \frac{1}{T} \int_0^T Z_V(\tilde{t}) \left(\varepsilon g_{syn} S_{LC}(\tilde{t} + \phi) (V_{LC}(\tilde{t}) - E_{syn}) \right) d\tilde{t}$$

and

$$\varepsilon\omega_j = \frac{1}{T} \int_0^T Z_V(\tilde{t}) \left(\varepsilon \tilde{g}_{Lj} (V_{LC}(\tilde{t}) - E_L) \right) d\tilde{t}.$$

Subtracting the phase equation for neuron 1 from that of neuron 2, the dynamics are reduced to a single equation that governs the evolution of the phase difference between the cells, $\phi = \phi_2 - \phi_1$

$$\begin{aligned} \frac{d\phi}{dt} &= \varepsilon(\omega_2 - \omega_1) + \varepsilon(H(-\phi) - H(\phi)) \\ &= \varepsilon(\Delta\omega + G(\phi)), \end{aligned} \quad (15)$$

where $\varepsilon\Delta\omega = \varepsilon(\omega_2 - \omega_1)$ is the difference between the intrinsic frequencies of the neurons due to their heterogeneity in leakage conductance.

Note that the function $G(\phi)$ or “ G -function” can be used to easily determine the phase-locking behavior of the coupled neurons. The fixed points of Eq. 15, which correspond to the phase-locked states of the pair of neurons, are given by $G(\phi^*) = -\Delta\omega$. If $G'(\phi^*) < 0$, then the phase-locked state with phase difference ϕ^* is stable; if $G'(\phi^*) > 0$, then the phase-locked state is unstable.

Figure 3 shows an example G -function for parameters corresponding to the limit cycle solution $X_{LC}(t) = [V_{LC}(t), n_{LC}(t), S_{LC}(t)]^T$ and the iPRCs $Z(t) = [Z_V(t), Z_n(t), Z_S(t)]^T$ shown in Fig. 1. For identical neurons ($\Delta\omega = 0$), this system has two steady states: synchrony ($\phi^* = 0, T$), which is unstable, and antiphase ($\phi^* = T/2$), which is stable. The addition of the heterogeneity shifts the phase-locked states of the coupled neurons. For example, if neuron 1 is made to be slightly faster than neuron 2 ($\Delta\omega < 0$), the stable antiphase state will be shifted to a phase difference that is less than $T/2$ and the unstable synchronous state will be shifted to a positive phase difference. This is seen in Fig. 3 when $\Delta\omega = -0.05$ and -0.1 . Furthermore, if $\Delta\omega$ is decreased further (below $\Delta\omega \simeq -0.13$), a saddle node bifurcation occurs in which the fixed points associated with stable and unstable phase-locked states collide and annihilate each other. This corresponds to the loss of 1:1 phase-locking.

Appendix: Computing the iPRC Using the Adjoint Method

As mentioned previously, the major practical asset of the singular perturbation approach to deriving phase models (Malkin 1956; Neu 1979; Ermentrout 1981) is that it provides a method to efficiently compute the iPRC for model neurons. Specifically, the iPRC is a T -period solution to

$$\frac{dZ}{dt} = -DF(X_{LC}(t))^T Z \quad (16)$$

subject to the normalization constraint

$$Z(0) \cdot X'_{LC}(0) = 1. \quad (17)$$

This equation is the adjoint equation for the unperturbed model neuron (Eq. 1) with $\varepsilon = 0$, i.e., $\frac{dX}{dt} = F(X)$ linearized around the limit cycle solution $X_{LC}(t)$.

In practice, the solution to Eq. 16 is found by integrating the equation backwards in time (Williams and Bowtell 1997). The adjoint system has the opposite stability of the original system Eq. 1, which has an asymptotically stable T -periodic limit cycle solution. Thus, we integrate backwards in time from an arbitrary initial condition so as to dampen out the transients and arrive at the (unstable) periodic solution of Eq. 16. To obtain the iPRC, we normalize the periodic solution using Eq. 17. This algorithm is automated in the software package XPPAUT (Ermentrout 2002), which is available for free on Bard Ermentrout's webpage www.math.pitt.edu/~bard/bardware/.

Wilson-Cowan Equations

► Large-Scale Neural Networks: Vision

Wilson-Cowan Model

Zachary P. Kilpatrick
Department of Mathematics, University of
Houston, Houston, TX, USA

Definition

The Wilson-Cowan model describes the evolution of excitatory and inhibitory activity in a synaptically coupled neuronal network. As opposed to being a detailed biophysical model, the system is a coarse-grained description of the overall activity of a large-scale neuronal network, employing just two differential equations. Key parameters in the model are the strength of connectivity between each subtype of population (excitatory and inhibitory) and the strength of input to each subpopulation. Varying these generates a diversity of dynamical behaviors that are representative of observed activity in the brain, like multistability, oscillations, traveling waves, and spatial patterns.

Detailed Description

Many regions of the brain process large-scale spatiotemporally structured inputs (Wang 2010). Understanding the resulting neural activity requires macroscopic models that can track the average firing rate across many areas of a neuronal network (Ermentrout 1998). This was the approach in the seminal work of Wilson and Cowan (1972, 1973), who derived effective equations for the macroscopic behavior of a large network of neurons. The approach is analogous to using statistical thermodynamics to relate the Brownian motion of particles to a mean ensemble motion of a whole fluid or gas (Reichl and Prigogine 1980). Thus, Wilson and Cowan

(1972, 1973) derive an effective system for the mean field of an underlying statistical process.

Space-Clamped Model

Starting with a large population of densely coupled neurons, Wilson and Cowan (1972) derived effective equations for the proportion of cells in a population that are active per unit time. Crucially, the effective behavior of the population relies on interactions between excitatory and inhibitory cells, where $a_e(t)$ and $a_i(t)$ are the proportion of excitatory and inhibitory cells firing per unit time at instant t . Thus, $a_{e,i}(t) = 0$ corresponds to a low-activity resting state. Excitatory (inhibitory) neurons make their neighbors more (less) likely to become active, and activation is a nonlinear function $F_e(F_i)$ of the presently active proportion of cells. These assumptions yield the system

$$\begin{aligned} \tau_e \frac{da_e}{dt} = & -a_e(t) \\ & + [1 - r_e a_e(t)] F_e(w_{ee} a_e(t) - w_{ei} a_i(t) + I_e(t)), \end{aligned} \quad (1a)$$

$$\begin{aligned} \tau_i \frac{da_i}{dt} = & -a_i(t) \\ & + [1 - r_i a_i(t)] F_i(w_{ie} a_e(t) - w_{ii} a_i(t) + I_i(t)). \end{aligned} \quad (1b)$$

Thus, the activity variables $a_{e,i}(t)$ obey first-order kinetics with timescales $\tau_{e,i}$, tracking the response of each subpopulation. The nonlinearities are typically chosen to be sigmoidal

$$F_j(x) = \frac{1}{1 + e^{-\gamma_j(x - \theta_j)}}, j = e, i, \quad (2)$$

where the gain γ_j and threshold θ_j can depend on the population type $j = e, i$. The argument x is a weighted sum of the proportion of active excitatory and inhibitory cells, where $w_{jk} \geq 0$ describes the strength of connection from cell type k to j . The system Eq. (1) also captures the refractory dynamics of both populations, defined by the prefactors $[1 - r_j a_j(t)]$, tracking the period of time

during which cells are incapable of stimulation following an activation. This term has often been neglected in subsequent considerations of the model, and Pinto et al. (1996) showed that it effectively rescales the parameters of the nonlinearities $F_{e,i}$. The inputs $I_j(t)$ represent the sum of currents arriving to population j from external sources (e.g., other brain areas or an implanted electrode). The derivation of Eq. (1) also presumes important characteristics of time-dependent rates $a_{e,i}$ for large-scale computation that are captured by temporally coarse-grained traces (Wilson and Cowan 1972).

By performing a phase plane analysis on Eq. (1), to find the stability of fixed points $(a_e(t), a_i(t)) = (\tilde{a}_e, \tilde{a}_i)$ Wilson and Cowan (1972) observed two typical modes of behavior. First, when the strength of synapses between excitatory cells is sufficiently strong, multiple stable fixed points can exist: a high excitation and a low excitation state. Alternatively, when the strength of connections between inhibitory subpopulation is sufficiently weak, the system Eq. (1) supports limit cycle solutions. In these limit cycles, a small proportion of active excitatory cells kindle other cells' activation, eventually recruiting inhibitory cells that turn all cells off, starting the cycle over. Thus, Wilson and Cowan (1972) presented a simple mechanism for oscillations in firing rate activity, an ubiquitous neural phenomenon (Wang 2010). Notably, mutually inhibitory models were adapted from Eq. (1) by considering an arbitrary number N of neural populations coupled together solely by inhibition. Each population is then conceived of as representing a separate stimulus or percept, making such models ideal for studying the neural mechanisms of decision making (Usher and McClelland 2001; Bogacz et al. 2006) and perceptual rivalry (Laing and Chow 2002; Wilson 2003).

Spatially Structured Model

The model Eq. (1) ignores potential spatial structure in the network of synaptic connections or the external inputs to the network. Upon considering a spatially organized network of neurons, Wilson

and Cowan (1973) described the connectivity between different regions of the network using functions that depend on the position of the origin y and target x of a synaptic connection. In doing so, this yields a set of partial integral equations

$$\tau_e \frac{\partial a_e(x, t)}{\partial t} = -a_e(x, t) + [1 - r_e a_e(x, t)] F_e(w_{ee} * a_e - w_{ie} * a_i + I_e(x, t)) \quad (3a)$$

$$\tau_i \frac{\partial a_i(x, t)}{\partial t} = -a_i(x, t) + [1 - r_i a_i(x, t)] F_i(w_{ei} * a_e - w_{ii} * a_i + I_i(x, t)) \quad (3b)$$

where $w_{jk} * a_k$ is a convolution operator

$$w_{jk} * a_k = \int_{\Omega} w_{jk}(x - y) a_k(y, t) dy \quad (4)$$

representing the effective drive to population j at location x received from population k . Writing the network of synaptic interactions as a spatial convolution gives a more general definition of the geometry of the network than discrete neural network models that use matrices to describe connectivity (McCulloch and Pitts 1943; Hopfield 1984). Typical weight functions are the Gaussians

$$w_{jk}(x - y) = k_{jk} e^{-(x-y)^2 / \sigma_k^2} \quad (5)$$

which represent a distance-dependent decay in cortical connectivity. The spatial domain Ω can be of arbitrary dimension and size, but it is usually taken to be one or two dimensional as we describe below. The nonlinearities $F_{e,i}$ are often sigmoids Eq. (2), and refractoriness is modeled by the term $[1 - r_j a_j]$ as before. We note that in Eq. (3), it is possible to track the spatiotemporal evolution of inputs, not just the temporal evolution. A key assumption in deriving Eq. (3) is that the intricacies in firing rate variation that occur on very fine spatiotemporal scales can be coarse-grained (Wilson and Cowan 1973). This results in a system of partial integrodifferential equations that are amenable to mathematical analysis (Bressloff 2012).

Applications and Extensions

Originally, Wilson and Cowan (1973) developed the spatial model Eq. (3) to analyze neural hysteresis phenomena related to binocular vision. Since then, the system Eq. (3) has been used as a canonical model of visual cortical activity, since higher mammals' visual systems possess spatially organized feature maps (Hubel and Wiesel 1977). For instance, a mathematical theory of geometric visual hallucination patterns was developed by using symmetric bifurcation theory to analyze the emergence of Turing patterns when Eq. (3) evolved in $\Omega = \mathbb{R}^2$ (Ermentrout and Cowan 1979; Bressloff et al. 2001). Aside from spontaneous visual experience, the model Eq. (3) was also modified with an additional equation for Hebbian plasticity in the weights w_{jk} to understand the spontaneous organization of the cortical feature maps that underlie the processing of spatiotemporally structured inputs (Kohonen 1982). All the periodically ordered maps for certain features like ocular dominance and orientation selectivity can be incorporated into Eq. (3) by employing the appropriate spatial domain Ω (Ben-Yishai et al. 1995; Bressloff and Cowan 2003).

Since its inception, the system Eq. (3) has also been used to model a variety of other sensory, memory, and motor processes. Early on, work in a related model to Eq. (3) showed the combination of short-range excitation and long-range inhibition ($\sigma_e < \sigma_i$ in Eq. (5)) could stabilize persistent activity into the shape of a bump (Amari 1977). Thus, even in the absence of inputs $I_i(x, t)$, the system Eq. (3) can support a nontrivial profile of spatiotemporal activity due to the activity sustained by recurrent excitation w_{ee} . This mechanism has now been used extensively as a model of visuospatial working memory (Camperi and Wang 1998), since the spatial position of a transient stimulus is known to be stored in cortex as persistent activity that can last for up to several seconds (Durstewitz et al. 2000). Related to this, lateral inhibitory networks have also been employed as idealized models of spatial navigation (Samsonovich and McNaughton 1997) and movement preparation (Erlhagen and Schoner

2002), whose neural correlates are also known to be spatially localized, tuned, persistent activity.

The Wilson-Cowan model Eq. (3) has been extended in many ways to account for the rich diversity of currents, synaptic processes, and fluctuations present in the brain. Spike rate adaptation was considered by Hansel and Sompolinsky (1998), who showed that this resulted in traveling waves of neural activity. Similar phenomena arise upon considering the effects of short-term plasticity (Kilpatrick and Bressloff 2010), which dynamically modulates the strength of the synaptic weight functions w_{jk} . Finally, there has been a lot of interest recently in capturing the effects of fluctuations on spatially extended rate models like Eq. (3). Early efforts have simply considered additive spatiotemporal noise processes (Hutt et al. 2008), but a great deal of progress has been made in deriving effective Langevin equations from stochastic neural networks using path integral methods (Buice and Cowan 2007) or a system size expansion (Bressloff 2012).

Wireless microstimulation; Wireless stimulators

Definition

Electrical currents for neural stimulation have conventionally been delivered via metal wires to

the electrode that is in contact with the tissue. The wire connections attached to these rigid electrodes, floating in a very soft medium like neural tissue, not only damage the surrounding cells from tethering forces but also limit the longevity of the implant due to wire breakage in chronic implants. Wireless transfer of stimulus energy as well as the pulse parameters to a floating electrode or an array of electrodes has gained interest in recent years as a method to eliminate the associated problems with tethering wires. Considering the properties of the neural tissue, different types of energy transfer mechanisms have been proposed for energizing the implant wirelessly: electromagnetic radio-frequency (RF), optical, and acoustic waves. The implanted electrode(s) may or may not have active electronics for storing the pulse parameters. Active devices also require an energy storage mechanism for powering the circuit. On the other hand, passive devices that can instantaneously convert the incident energy into the electric stimulus do not need to store energy or require programming, often maximizing the stimulus energy and implantation depth.

The enthusiasm for replacing wired stimulators with wireless versions is primarily motivated from the complications that arise from tethering forces associated with the micromotions of the electrode assembly, the risk of infection from percutaneous connections, and the failures from wire breakage. Additionally, with passive versions of the wireless devices, the electrode shank needed for housing

the electrode contacts and the connecting wires is no longer needed, thus displacing less tissue. This entry discusses the critical parameters associated with microstimulators that use wireless links. The wireless microstimulation concept is illustrated in Fig. 1.

Detailed Description

Active and Passive Microstimulators

The stimulation pulse parameters (amplitude, duration, frequency) need to be adjustable in most neuroprosthetic applications to achieve the best results. Thus, when discussing wireless microstimulators, it is useful to classify the devices as either active or passive, depending on whether the device is actively controlling the stimulation signals or if the device passively converts transmitter energy directly into electrical stimulation. In the passive case, the pulse parameters must be controlled by the external unit in the form of energy packages. Passive wireless devices can have the benefit of maximizing the device area for energy conversion. Active devices often contain complex electronics that control the pulse parameters and stimulus rates and must dedicate area to this function. On the other hand, active wireless devices can operate autonomously with minimal intervention and only at times when the pulse parameters need to be modified or the battery needs to be recharged.

Wireless

Microstimulators,

Fig. 1 Illustration of a wireless microstimulator. Energy can be transmitted to the stimulator using RF, optical, or acoustic waves. Current generated by the microstimulator travels from the anode to the cathode of the device, inducing action potentials in nearby neurons

Energy Transfer

Battery Storage

The stimulus energy may be provided from a battery incorporated into the implant. The latest version of the BION™ is a good example of an implantable wireless stimulator with a battery (Loeb et al. 2001; Schulman 2008; Kane et al. 2011). Battery systems are attractive because they do not depend on a wireless link for uninterrupted operation, and they are not bound by energy transfer limitations inherent to wireless energy transfer through tissue. Drawbacks include their large volume, required for the battery, and battery capacity. Batteries need to be replaced or recharged (through a wireless link), limiting their use in chronic implants. The BION™ stimulator reportedly requires charging every few days.

RF Electromagnetics

The most common wireless paradigm for microstimulation is via RF links due to the low absorption of these electromagnetic waves in the tissue. The size of the loop antenna, critically the receiver, can be the limiting factor in the case of RF-powered devices (Rabaey et al. 2011). Other important parameters are whether to use near-field inductive coupling (for increased power coupling efficiency, relevant at lower frequencies) or far-field coupling (larger distances at higher frequencies, but with lower coupling efficiencies) and the RF center and bandwidth (Poon et al. 2010). Heetderks in the 1980s analyzed this system and defined the characteristics of magnetically coupled power transfer systems (Heetderks 1988). Magnetic induction devices work best when the external exciter coil and the internal power receiving coil are in their near fields. This means that very small loop antennas associated with injectable-sized neurostimulators must be located relatively close to the body surface. Otherwise, the nearly cubic rate of decay of the magnetic intensity in the loop far field requires substantial power generation and battery drain on the body surface exciter to overcome such losses.

It is worth noting that radio waves will be shortened when traveling through the tissue,

allowing smaller antennas as compared to those used in air. This can become important at microwave frequencies above 300 MHz, reducing the antenna size of the microstimulator.

Direct conversion of microwave energy to generate neurostimulation electrical pulses in potentially injectable devices has been reported (Towe et al. 2012). These devices are basically small dipoles of about 1 cm length and 800 μm or less diameter that are capacitively coupled by way of electric field coupling to a body surface antenna (Towe et al. 2012). These devices differ from more traditional methods of powering neuroimplants by low-frequency magnetic induction coil systems that depend primarily on the magnetic field component of the EM wave to induce power into open-loop induction coils implanted in tissue.

Advantages

Powering implants at microwave frequencies through electric field coupling has been treated at length by Poon et al. who showed that efficient power transfer to moderately deep implanted devices can be accomplished at GHz frequencies (Poon et al. 2010). Emission of significant RF power from a body surface transmitter and radiating antenna is limited by most countries to specific frequency bands. In the USA, unlicensed operation is permitted at 915 MHz and 2.45 GHz defined as the industrial, scientific, and medical (ISM) bands. These frequencies can be used for efficient energy transfer, as reported by Poon.

Disadvantages

Microwave penetration into the human body varies substantially depending on the tissue type and frequency. Tissue heating is the main concern at elevated microwave pulse powers needed to provide sufficient energy for an injectable size implant at a depth of 5–7 cm. Such an application might be, for example, for pain relief in the spinal canal. The specific absorption rate (SAR) is the primary indicator of microwave dosimetry in biological objects. The regulatory limit in the USA, for example, is 1.6 W/kg for 1 g of tissue (Poon et al. 2010). Since neurostimulation currents are pulsed and have low duty cycles (typically on the

order of 1%), the peak pulse power of microwave radiation can be relatively large, for example, in 5–20 W and higher while maintaining an SAR-limited average power of less than a watt applied to the skin surface by an antenna over the implant. By using relatively high peak pulse powers in the tens of watts range, the microwave exciter antenna can be spaced away from the body by fractions of a meter (Towe et al. 2012) if the stimulation current demands of the implant are low, e.g., less than a milliamperere with 250 μ s pulse widths at 10 Hz.

Current State of the Art

In reported works, implanted microwave dipoles are generally untuned to the microwave frequency in order to achieve small size, and so they depend entirely on capacitive electric field coupling through the tissue. Reported versions have the dipole coupled to a low-threshold Schottky diode that rectifies the high-frequency microwave and turns it into a high-frequency pulsating DC current that is functionally applied directly to the excitable nerves and tissues.

Optical

Microstimulators using light in the near-infrared (NIR) spectrum (wavelengths on the order of 700–900 nm) can be used for wireless power transfer. NIR light has relatively low absorption and low scattering in the neural tissue, as compared to visible light, and it can be converted into electric currents with high efficiencies using semiconductors. Advantages of the optical method include the ability to focus light before the beam enters the tissue, which maximizes energy transfer, and that optical radiation frequency bands are not regulated by governments, unlike RF waves. Floating light-activated microelectrical stimulators (FLAMES) have been shown to produce functional forelimb forces via stimulation of the rat spinal cord gray matter (Abdo et al. 2011b). An optical stimulator with a fiber-optic pigtail has also been demonstrated to generate muscle activation by stimulation of a frog sciatic nerve (Song et al. 2007). Fiber-optic connections prevent classifying this approach as a wireless method; nonetheless, a pigtail fiber connection has a potential to increase the number of optical channels easily

without adding a new fiber for each additional stimulation channel. Active stimulators with optical links are still under development and have yet to be demonstrated *in vivo* (Freedman et al. 2011).

Advantages

Optical power transfer for passive neurostimulation is a relatively less complex method of energy transfer due to the lack of carrier-wave generating systems needed for radio and acoustic techniques. Laser diode infrared emitters and photodetectors are readily available. When powering neurostimulators placed within a few millimeters, they can be more efficient in energy conversion compared to other methods. The elimination of a rigid substrate and the electrode shank is a shared benefit by all wireless methods with a single stimulation channel. The FLAMES are reportedly in the submillimeter range and therefore suitable for CNS applications with minimal tissue replacement. Optical methods also allow addressing of multiple single-channel stimulators via wavelength selectivity.

Disadvantages

Light scattering in the tissue makes it difficult to activate a large number of disjoint stimulators. Passive stimulators of reported designs intrinsically generate monophasic pulses and so must either use classic capacitive coupling to perform electrode charge balancing or engage the use of an integrated circuit for more precise control which then entails additional complexity and requirements for its own powering. All reported passive wireless stimulators, including RF, optical, acoustic, and microwave excited, have an intrinsic orientation dependency in their coupling to the body surface exciters. For example, photodetectors must be oriented planar relative to the optical driving source. This requires that the physician would have to be aware of this with device implantation.

Current State of the Art

A small number of optically powered microstimulators are currently being researched. Wavelength-selective optical devices have

reported efficiencies around 11% (Abdo et al. 2011b) and 43% (Song et al. 2007) for non-wavelength-selective devices.

Stimulation Depth

Although NIR light penetration into the neural tissue is greater compared to visible light, the light attenuation is still relatively strong. In the rat brain, the intensity was reduced to 1.85% of the subdural intensity at 1000 μm and to 0.15% at 2000 μm (Abdo et al. 2013). However, the prototype devices were able to stimulate the spinal cord gray matter and produce forces above 0.8 N (Abdo et al. 2011b) at an implantation depth of 2.35 mm. Scattering of light photons is the dominant effect that limits the penetration depth in the neural tissue, although the g factor (diversion of photon from straight path after scattering) strongly favors the forward direction ($g = \sim 0.9$). The scattering coefficient, which indicates the number of scattering events on average per unit length of the photon path, is larger than 100 per cm in the rat brain (Abdo et al. 2013). Thus, the primary limitation on stimulus power is the temperature increase near the surface where the photons enter the tissue. Direct measurements of temperature with a micro-thermocouple sensor suggest that the power level used in the rat spinal cord (Abdo et al. 2011a) study would only cause a small fraction of a degree elevation in temperature.

Acoustic

Ultrasonic techniques can efficiently transfer energy to a microstimulator through mechanical vibrations at high frequencies. The work by Towe et al. showed that millimeter-order-sized chips of PZT were capable of intercepting sufficient ultrasound power to accomplish direct conversion of the energy to do neurostimulation through 7 cm or more of tissue while maintaining a form factor that was consistent with direct tissue injection of the neurostimulator (Towe et al. 2009). These systems depend on a body surface ultrasound exciter to generate the needed pulse characteristics modulated in the ultrasound carrier wave to evoke the desired neurostimulation waveform from the piezoelectric converter system in tissue.

Advantages

The advantage of acoustic powering of implants is that relatively high-energy densities can be carried by ultrasound waves compared to electromagnetic and optical techniques, and this improves power transfer and allows significant functional depths. This is because they are waves in matter rather than coupled through the electric or magnetic permeability of free space. High frequencies of ultrasound in the MHz region are associated with high accelerations but minuscule displacement of the tissue, with the end result being significant momentum carried by the waves compared to a similar amount of power in generating, for example, an RF magnetic field. Another advantage is that unlike electromagnetic field frequencies below 400 MHz used for power and communication with conventional neurostimulators, ultrasound energy in the medical frequency region can be focused into tight beams by small acoustic lenses and hence has high-energy transfer efficiency in targeting a neuroimplant at a known location. This focality of ultrasound can thus result in reduced battery power consumption in some cases compared to lower-frequency magnetic induction techniques, particularly where the neural implant lies deep in the tissue to small devices where magnetic coupling techniques require relatively large coils.

Disadvantages

Ultrasound energy is strongly absorbed by the bone at MHz frequencies, and so ultrasound losses along the path length through the bone are severe amounting to 3–5 dB/cm (Wells 1977). The losses result from both absorption and scattering of the sound and can cause a disproportionate amount of the beam energy to be deposited in the bone leading to concerns about temperature rise. Ultrasound dosimetry is a limitation if trying to reach targets through the skull in the deep brain or possibly underneath the vertebrae to reach the spinal cord. Employing highly focal transducers to further reduce battery drain or reach deep implants is accompanied by the need to keep the skin surface or shallowly implanted transducer aimed with precision at the implant, a task which may not be practical in all patient applications

where the patient wears the ultrasound exciter on his body. A potential method to overcome this problem was reported to be based on electronic feedback by way of monitoring remote skin potentials produced by an implanted neurostimulator and the use of an ultrasound scanning beam (Gulick and Towe 2012).

Current State of the Art

Conversion efficiency of ultrasound energy by piezoelectric elements integrated as part of a neurostimulator system can be on the order of 10% or more (Ozeri and Shmilovitz 2010). Ultrasound attenuation due to viscoelastic path losses in the tissue amounts to 1–3 dB/cm at 1 MHz, depending strongly on the tissue along the beam path and the ultrasound frequency. Ultrasound path losses increase nonlinearly as the frequency increases (Wells 1977), and so optimal frequencies for power transfer are not the same as diagnostic ultrasound imaging but rather lower and typically in the range of 500 kHz to 1 MHz depending on the path length to the powered implant.

Stimulation Depth

The primary biological effects of concern using ultrasound as an energy transfer medium to an implant are those of tissue heating. FDA limits medical diagnostic ultrasound average intensities to 720 mW/cm² and peak pulse intensities to 190 W/cm² (Center for Devices and Radiological Health 2008). The safe peak pulse intensity specification means that very large 40–50 dB path losses of ultrasound can be tolerated since typically less than a milliwatt is required for neurostimulation.

Concerns and Limitations of Wireless Microstimulators

Tissue Heating

Essentially all reported energy transfer methods are limited in their ability to power deeply implanted device by their energy dissipation along the tissue path length. This dissipated energy can cause tissue heating. Tissue, especially

water-rich tissues, such as the brain, muscles, or skin, can absorb and convert significant amounts of RF, optical, acoustic, or microwave energy into heat. It is imperative that the temperature at any focal point in the tissue is kept at minimal. A temperature elevation limit of 0.5 °C may be taken as a conservative value until more definitive data becomes available, based on the finding that 1 °C produces observable changes (Kiyatkin 2004).

Material Safety

Like all biomedical implants, they must be hermetically sealed and not release any harmful chemicals into the tissue. Encapsulation and sealing sufficient to last a person's lifetime can add significantly to the overall size of these devices. Whether active or passive, implantable stimulators are typically made with semiconductors that may contain materials, such as copper oxides or arsenic oxides, and can be toxic. Solutions include encapsulation of the microstimulator with dielectrics, such as ceramics, glass, and/or organic polymers, such as parylene-C or polyimide.

Channel Selection

Effective microstimulation for some applications such as brain-machine interfaces or spinal cord stimulators requires addressability of multiple different stimulation sites or channels. Optical energy transfer methods can permit some spatial directivity and by an ability to encode, over a range, in infrared wavelengths. Digital encoding for optical device selection is technically possible (Freedman et al. 2011). However, simplicity and some efficiency are lost with the requirement to divert received power to digital logic. Such digital approaches that incorporate microwave or ultrasound powering methods have not been reported so far. Multichannel ultrasound is enabled in principle by the ability to scan a focal beam over a tissue region and serially power multiple devices.

Bipolar Versus Monopolar

Wireless stimulators contain both cathodic and anodic contacts on the device, and thus, the inter-contact distance is limited by the device

size. Multichannel, active stimulators may have a few millimeters between the cathode and anode, and they may be considered to behave as monopolar stimulators especially if the reference electrode is significantly larger than the stimulating contacts. However, with single-channel passive devices, the primary objective is to make the device as small as possible, perhaps a few hundred microns, to minimize the tissue replacement. Thus, the cathodic–anodic contact distance is similarly very short, and the device should be considered as a bipolar stimulator.

Device Size

An ideal microstimulator would displace zero volume in the tissue. Realistically, a stimulator will use the minimum volume needed. In bipolar stimulation, the stimulation strength decreases steeply with distance from the electrodes (Sahin and Píkov 2011). However, simulations suggest that the structures in a volume that is in the same order as the size of the device should be feasible to stimulate while keeping the current in the microampere range (Abdo and Sahin 2011).

Device Geometry and Contact Placement

Large aspect ratios of device geometry should be preferred to maximize the anode–cathode separation and thus the stimulation effect for a given stimulus current. In a 3D device fabrication process, the contacts can be placed at each end of a longitudinal structure. This may be difficult to achieve using standard micro-fabrication processes that are typically applied on wafer-like structures. If the contacts have to be placed on the top surface of a rectangular prism with dimensions in proportions of 2:2:5, the stimulus strength reduces by 8.5% compared to the case where the contacts are placed on each end (2:2 surfaces, (Abdo and Sahin 2011)). A high aspect ratio is also advantageous for insertion of the stimulator into the targeted neural tissue. Electronic device fabrication utilizes only a very shallow region of the semiconductor on the surface, allowing the total device thickness to be reduced down to 50 μm or less. Mechanical strength of the semiconductor substrate becomes the practical limiting factor that determines the maximum aspect ratio

of the structure that renders the device too fragile under bending. In the case of acoustic devices, similar issues apply to piezoelectric ceramic materials like the PZT, in addition to the fact that the piezoelectric device geometry also determines its resonance frequency at which the energy harvesting efficiency is at a maximum. With all three energy transfer paradigms considered here, the device orientation inside the tissue with respect to the external energy source is critical in order to maximize the energy transfer.

Contact Material

The interface between the stimulator and tissue is a critical parameter because the available energy in a wireless microstimulator is always limited. Thus, materials with high charge-injection capacity are desired for the contacts of a wireless microstimulator. Examples include porous platinum or platinum–iridium alloys, sputtered or electroplated iridium oxide, titanium nitride, and conductive polymers like PEDOT (Cogan 2008). The area and the roughness of the electrode contacts also have a significant effect on the charge-injection capacity and typically have a nonlinear relationship between geometric area and the charge-injection capacity. For example, a sputtered iridium oxide microelectrode with a 200 nm surface coating has a charge-injection capacity of 5.3 mC cm^{-2} when the area is approximately $2000 \mu\text{m}^2$ but decreases to 1.7 mC cm^{-2} with a relationship that decays exponentially with increasing surface area.

Voltage Compliance

Simulations suggest that the output voltage of a microstimulator is an important parameter to optimize the energy transfer from the implant to the surrounding neural tissue (Abdo and Sahin 2011). There is a trade-off between the contact size and the required device output voltage. The electrode–electrolyte interface voltages at the contacts are in series to the voltage that develops across the tissue. The device output voltage (compliance) has to be large enough to accommodate the electrode impedance, which is inversely proportional with the contact size for a given material (i.e., charge-injection capacity), and the device current.

Therefore, one can choose large contacts, allowing the device surface area to increase, in return for a smaller output compliance requirement. Thus, larger contact sizes permit a smaller output voltage and so allow a larger stimulus current assuming the total stimulus energy is constant. Conversely, if the device electrode surface area has to be kept below a certain level, this dictates an upper bound for the stimulus current as well. In conclusion, the design of a microstimulator is an optimization problem that intertwines geometrical and electrical parameters of the device.

Representative Examples

RF (Inductive Coupling)

The BION™ neural stimulator (Loeb et al. 2001; Schulman 2008; Kane et al. 2011) is an example of an active floating microstimulator that uses magnetic inductive RF coupling (2 MHz) to transfer energy and also incorporates pulse synthesis and decoding of channel data for neural stimulation. It has an internal capacitor which integrates energy supplied continuously over time that is then metered out according to digital instructions. Externally, the exciter is characterized by a battery pack and relatively large exciter applicator compared to optical or ultrasound methods. The exciter is worn as a coil placed over the implant and connected to a remote battery pack. The diameter of the implant device is 2 mm and the length ranges from 10 to 16.7 mm. Current generations of the device have 256 individual channels that can be independently addressed and a custom ASIC as a pulse former. Stimulation parameters allow currents to be generated in the hundreds of microamperes, up to

40 mA, with voltage compliance values between 8.5 and 17 V. Using iridium and tantalum or platinum–iridium electrodes, the BION™ can deliver up to 50 pulses per second. A distinguishing feature of the BION™ stimulator is its hermetic sealing of either glass or ceramics. Accelerated moisture testing of recent devices shows excellent device reliability for use in multiyear implants.

Optical (NIR Coupling)

The FLAMES (Abdo et al. 2011b) neural stimulator is a passive floating microstimulator that uses diffused near-infrared light to transfer energy for neural stimulation. The device size is approximately $500\ \mu\text{m} \times 200\ \mu\text{m}$ and about $100\ \mu\text{m}$ thick and is shown in Fig. 2. The devices can be addressed by using different wavelengths of infrared light. Stimulation parameters allow currents to be generated on the orders of tens to hundreds of microamperes with voltage compliance values below 2 V. Contacts have been made out of gold coated with PEDOT for good charge-injection capacity under zero bias conditions. Other contact materials and long-term encapsulation with parylene-C are currently being investigated.

Acoustical (Ultrasonic Coupling)

Ultrasound-powered microstimulators have been demonstrated (Towe et al. 2009). In this system, a 1 MHz ultrasonic emitter with a diameter of 26 mm at a distance of 12 cm was used. A piezoelectric receiver, made of PZT-5A, with a 1.13 mm diameter and 1 mm thickness, was used. In a Sprague-Dawley rat, currents on the order of a milliamperere were generated with average powers between $10\ \text{mW}/\text{cm}^2$ and $147\ \text{mW}/\text{cm}^2$. Figure 3 shows a photograph of this type of device.

Wireless Microstimulators, Fig. 4 Photograph of a 915 MHz microwave-powered passive neurostimulator (center) along with a 16-gauge syringe needle and a multi-electrode catheter used for spinal neurostimulation (Medtronic)

Microwave Coupling

Coupling through primarily the EM wave electric field component at microwave frequencies using a thin dipole antenna doubling as an electrode system was demonstrated in the stimulation of a rat sciatic nerve (Towe et al. 2012). An example of this type of device is shown in Fig. 4. This device has a size on the order of 800 μm in diameter and 1.5 cm length, and it was constructed using a low-bias Schottky diode connected to an internal 100 μm diameter platinum wire dipole antenna. This device operates untuned in the ISM band at 915 MHz (US) or 2.45 GHz (international). It

develops milliampere-order currents at 7 cm tissue depths when pulsed at 10 W peak.

Definition

Wiring principles determine the topological and spatial layout of connections and nodes of neural

networks. The organization of brain connectivity is subject to several, synergistic or conflicting, constraints, such as low metabolic cost, restrictions of white matter volume by the skull size, and high efficiency of signal processing as reflected in a small number of processing steps.

Detailed Description

Brain connectivity can be analyzed from the perspective of topological or spatial properties of the network. Traditionally, wiring principles have been discussed in the context of spatial properties of brain networks, that is, defined by the location of network nodes and the length of connections among them.

Wiring can be considered at the local scale, reflected by axons and dendrites between individual neurons, or at the global scale, by fiber tracts among brain regions. A lower bound for the wire length is the Euclidean distance between two connected network nodes, measured as straight line between the nodes' mass centers. As some fibers are curved, the three-dimensional trajectory can give a more accurate representation of fiber lengths in a system. However, traditional anatomical tract-tracing techniques make it difficult to determine axonal trajectories directly. Alternative approaches focus on fiber volume rather than connection length, taking into account both fiber length and fiber density (thickness).

While most connections in brain networks are formed at short distance, there exist a substantial number of long-distance connections in diverse examples of neural systems (Fig. 1). The wiring length distribution, in which the frequency of connection lengths decays with distance, can be best approximated by a Gamma distribution (see Kaiser et al. (2009) for details). On the one hand, long-distance connections are costly, in that their establishment and functional maintenance (e.g., action potential propagation) requires energy. On the other hand, long-distance connections can form topological shortcuts (Watts and Strogatz 1998) that may lead to faster and more efficient signal transmission and may result in accelerated reaction times (Kaiser and Hilgetag 2006).

Spatial Wiring Constraints

Neural networks should be spatially compact to minimize transmission delays, volume, and metabolic demands associated with neurite development and maintenance as well as signal transmission. It is important to keep in mind that different optimal wiring arrangements might exist for different scales of neural organization, from global systems (e.g., corticocortical connections) to local neuronal connectivity (Murre and Sturdy 1995).

Mechanisms through which a compact design may be achieved are (1) spatial growth models (e.g., Kaiser and Hilgetag 2004b; Kaiser et al. 2009) and (2) self-organization through axonal tension minimization (Van Essen 1997; Hilgetag and Barbas 2006).

The presence of connections involves structural metabolic costs (especially for myelinated

axons) as well as costs for transmitting action potentials (Laughlin et al. 1998; Laughlin and Sejnowski 2003). It is intuitive to assume that, in order to increase organismal fitness, these costs should be kept as low as possible (Cherniak 1992; Chklovskii et al. 2002; Wen and Chklovskii 2008) leading to the idea of wiring optimization.

Wiring optimization (Cherniak 1994; Chklovskii 2004) is often observed at the cellular level, including neural morphology (Cherniak 1992; Cherniak et al. 1999; Chklovskii et al. 2002; Wen and Chklovskii 2008) or connections between cortical maps (Chklovskii and Koulakov 2004). Optimization was also found for white matter volume (Wen and Chklovskii 2005). While these studies were often focused on mammalian brains, the economy of neural circuits was also studied in *Drosophila* (Rivera-Alba et al. 2011) and *Caenorhabditis elegans* (Varshney et al. 2011).

What is the actual evidence for minimal wiring in neural systems? Distributions for brain networks at different scales show mostly neighborhood connections but typically also have a substantial tail of long-distance projections. Thus, the networks are not strictly minimally wired. This observation resulted in a refined assumption of minimal wiring, component placement optimization (CPO): the optimal placement of components under the assumption of fixed connectivity (Fig. 2). In a network obeying CPO, any rearrangement of node positions, while keeping their connectivity fixed, would result in a higher total wiring length of the network. While initial evidence appeared to be in favor of CPO (Cherniak 1992, 1994; Chklovskii et al. 2002), analyses of more extensive and detailed datasets (e.g., Chen et al. 2006; Kaiser and Hilgetag 2006) contradicted the generality of CPO, showing that both *C. elegans* and macaque cortical networks do not obey CPO. Therefore, neural networks do not appear to be solely optimized for minimal wiring, and additional constraints on network organization should be considered.

Efficient Signal Processing

Structural connectivity alone, without actual information on network dynamics, can only be a proxy for information on signal processing. In analogy to highway systems, structural connectivity can indicate the existence and number of lanes of a highway, but not the actual

traffic. Nonetheless, the underlying network for information propagation, which is given by anatomical connectivity, may inform on the likelihood of functional connectivity (Stephan et al. 2009) and provide a lower bound on the potential processing speeds in neural systems-based transmission delays influenced by the metric length of a fiber (Swadlow 1991) and its myelination (Koch 2004).

Particularly, processing speed may be related to the number of links that, on average, has to be crossed from one node to another. This measure is called average shortest path (ASP) or characteristic path length (L) (Watts and Strogatz 1998). A now widely adopted related measure is global efficiency, the inverse of ASP (Latora and Marchiori 2001). Alternatively, one might only be interested in information transfer at the local level. The clustering coefficient (Watts and Strogatz 1998) shows what proportion of potentially existing links between the neighbors of a node (nodes that are directly connected to a node) actually exist. A more recent measure at this level is local efficiency, defined as the average value over all nodes of the inverse of the path lengths between neighbors of each node (Latora and Marchiori 2001). Generally, a low number of links in a path potentially reduce delays and increase the speed and reliability of processing.

Studies on macaque and *C. elegans* structural connectivity (Kaiser and Hilgetag 2006) indicate that the reduction of path lengths appears at least as important as the minimization of total wiring length (Fig. 3). These studies showed that there

Wiring Principles, Optimization,

Fig. 2 Approaches to alternative wiring (*top*). Swap node locations (here: nodes *A* and *D*) while connections of each node remain the same (*bottom*). Swap connections (here: blue lines) where the location but not the connectivity pattern remains the same

Wiring Principles, Optimization, Fig. 3 Wiring arrangement of neural networks compared to minimum and maximum case benchmark networks. (a) Actual total wiring length relative to the minimum wiring length solution (value “0,” yielded by simulated annealing of component positions) and to networks optimized for maximum total wiring length (value “1,” also yielded by simulated annealing). The wiring of the different neural networks lies close to the middle between minimum and maximum case

component arrangements. (b) The average shortest path length (characteristic path length) in neural networks relative to networks optimized for minimum path length (value “0,” yielded by simulated annealing of wiring organization) and maximum path length (value “1”). The topological path lengths of the biological neural networks are close to the lower bound of networks optimized for minimum paths. (Adapted from Kaiser and Hilgetag 2006)

Wiring Principles, Optimization, Fig. 4 Benefits of long-distance connections. (a) Facilitated synchronization of near and distant regions, (b) reduced internode

transmission delays, (c) reduced (cross-modal) interference, and (d) increased reliability of transmission. (Adapted from Kaiser and Hilgetag 2006)

are more long-distance connections than would be expected by component placement optimization. Long-distance connections, while carrying metabolic costs for establishment and signal propagation, have the benefit of reducing the average number of connections between nodes; in other words, long-distance connections are often shortcuts that reduce the ASP of neural connectivity.

Minimizing path lengths, that is, reducing the number of intermediate transmission steps in neural integration pathways, has several functional advantages (Fig. 4). First, the number of intermediate nodes, which may introduce interfering

signals and noise, is limited. Second, by reducing transmission delays from multiple internode connections, the speed of signal processing and, ultimately, behavioral decisions may be increased. Third, long-distance connections enable neighboring as well as distant regions to receive activation nearly simultaneously (Kaiser and Hilgetag 2004a; Masuda and Aihara 2004) and thus facilitate synchronous information processing in the system (cf. König et al. 1995; von der Malsburg 1995). Fourth, the structural and functional robustness of neural systems increases when processing pathways (chains of nodes) are shorter.

Each extra node introduces an additional probability that the signal is not transmitted that may be substantial. For example, failure rates for transmitter release in individual synapses are between 50% and 90% (Laughlin and Sejnowski 2003). Even when the signal survives, longer chains of transmission may lead to an increased loss of information. A similar conclusion, on computational grounds, was first drawn by John von Neumann (von Neumann 1958) by comparing the organization of computers and brains. Von Neumann argued that due to the low precision of individual processing steps in the brain, the number of steps leading to the result of a calculation (“logical depth”) should be reduced, and highly parallel computing would be necessary.

Complexity and Robustness

Complexity may be expressed as balance between measures of segregation and integration. One way to support this balance is through modularization, as demonstrated by graph evolution (Sporns et al. 2000). Modularity is a ubiquitous feature of brain connectivity (e.g., Hilgetag and Kaiser 2004; Meunier et al. 2009). Mechanistically, it may arise from an unequal spatial distribution of neural nodes (e.g., Chen et al. 2013) or from developmental time windows (Kaiser and Hilgetag 2007; Nisbach and Kaiser 2007). Network modularity also serves to support structural and functional robustness. Particularly, it increases the resilience to random node and link lesions. Hierarchical modularity also stabilizes self-sustained network activity (Kaiser and Hilgetag 2010). Thus, ubiquitous modularity of neural connectivity may be a reflection of constraints of complexity and structural and functional robustness.

Combination of Multiple Wiring Constraints

Combinations of different constraints on neural network organization are not yet very well explored, due to the large number of potential combinations (Kaiser and Hilgetag 2006). An exploration of the balance of minimal wiring and

minimal path length in a combined objective function (Chen et al. 2013) demonstrated that this trade-off is well served by networks with mostly neighborhood links (to save wiring) and global or local hubs (to reduce path lengths). However, as most biological networks do not have hubs that are as pronounced as predicted by this model, it can be speculated that network organization is affected by additional factors, such as robustness and protection against lesion of global hubs. Notably, the analysis of multiple constraints has recently been applied to functional connectivity, showing that many features of these networks can be captured by combining spatial distance and topological constraints (Vertes et al. 2012).

Summary

While a number of constraints, such as minimization of wiring length and processing steps, appear to play a role in shaping neural networks, no single constraint can completely explain the observed neural connectivity, and brain network organization likely arises from the combined, potentially antagonistic influence of multiple constraints.

Definition

Working memory is the ability to temporarily hold and manipulate information to produce goal-

directed behavior. Drawing biological plausibility from *in vivo* electrophysiological studies, models of working memory attempt to identify cellular, synaptic, and network mechanisms of working memory functions. Current theoretical frameworks largely focus on persistent activity which is thought to be the main neuronal correlate of active maintenance of information.

Detailed Description

All theoretical constructs of working memory (WM) rest on a key notion, which is that of “active maintenance” of information (Miyake and Shah 1999). The adjective “active” refers to the fact that the information being held is able to affect, or even interfere with, the processing of further incoming information. What are the neurophysiological correlates of “active maintenance”?

Electrophysiological investigation of WM is routinely conducted within the delayed-response paradigm. A sensory cue provided at the beginning of the trial must be used, following a delay period, to produce an appropriate (i.e., cue-dependent) motor response, possibly in combination with some additional information provided at the end of the delay. As cue information is mandatory for performance and hence must be maintained across the delay, delay-response paradigms engage WM. Extracellular recordings of neuronal activity in animals performing delayed-response tasks reveal that a large proportion of cells in several cortical regions, e.g., frontal and parietal, modulate their activity during the delay period (Amit and Mongillo 2003). In its basic form, this modulation consists of enhanced/suppressed single-cell spiking rate during the delay as compared to the pre-stimulus period. This rate modulation, also called persistent activity because it is maintained after stimulus removal, is the identifying criterion for “WM cells.” It is widely held that the prime function of persistent activity is active memory maintenance (Goldman-Rakic 1995; Fuster 2008).

The most popular theoretical account for the phenomenology of persistent activity is based on the notion of attractor network (Amit 1989). In

this account, the network underlying memory maintenance possesses multiple “preferred” states of activity (attractors), typically as a result of some learning process. These activity states, which consist of patterns of neuronal activity self-generated by the collective network dynamics, are stable in the absence of external inputs and differ by the spatial distribution of activity across the network (i.e., which cells are firing at which rate). External inputs to the network (e.g., as a result of stimulus presentation) can cause the network to switch state according to the following mechanism. A sufficiently strong external input will impose a specific pattern of neuronal activation within the network. When the input is removed, this activity state will evolve into the “closest” attractor state, that is, the one which is the most similar to the activity state imposed by the external input. Once reached, this state will persist until new stimulation. The state eventually selected by the network dynamics depends, thus, upon the specific input received. The existence of multiple attractor states, their stimulus selectivity and their stability, allow the network to keep track of previous inputs. Attractor models have been extremely successful in reproducing several features of observed patterns of neuronal activity in WM experiments (Amit and Mongillo 2003; Brunel 2003). Numerical simulations of biophysically realistic models of cortical circuits have shown that attractor dynamics is a robust property of the resulting collective dynamics (Wang 2001; Compte 2006). Despite these successes, experimental evidence for attractor dynamics being implemented in cortical circuits is far from being conclusive.

An alternative class of models posits that sustained changes in the firing rates are the result of single-cell mechanisms rather than an emergent property of the collective network dynamics. In this scenario, the single neuron possesses two stable states of activity: a quiescent state and a high firing rate state. External inputs can switch the neuron between states. Modeling studies of single-cell dynamics, which include a sufficiently detailed description of the kinetics of the various ionic channels present in real neurons, have shown that cellular bistability is possible. The

mechanisms proposed include high-voltage-activated calcium channels in combination with calcium-activated cationic currents, post-spike after depolarization induced by neuromodulation, and the nonlinear current-voltage curve of NMDA receptors (Marder et al. 1996; Durstewitz et al. 2000; Major and Tank 2004). Single-cell bistability has also been demonstrated in *in vitro* studies (Durstewitz et al. 2000; Major and Tank 2004). Models based on single-cell bistability come short in explaining the strong temporal irregularity of persistent activity. In numerical simulations as well as in *in vitro* studies, spiking in the high firing state is far more regular than the one observed *in vivo* (Major and Tank 2004; Compte 2006). On the other hand, they can easily explain memory maintenance of previously unexperienced stimuli which is, instead, problematic to account for in the attractor framework where new attractors are assumed to be formed through “slow” synaptic modifications.

The models described so far assume that memory is maintained by enhanced spiking activity. An alternative model proposes that memory is maintained through the fast, stimulus-dependent modifications of synaptic efficacies induced by short-term facilitation (Mongillo et al. 2008). Active maintenance through (temporary) changes in the efficacy of recurrent synaptic transmission offers several advantages. As the time scales associated to short-term facilitation (order of a second) are significantly longer than those associated to the membrane potential dynamics (order of tens of milliseconds), memory maintenance requires little spiking activity with correspondingly low metabolic costs. Electrophysiological studies have indeed shown that persistent activity can occur at quite low rates. Importantly, the temporary perturbation of the ongoing neuronal activity has little effect on the information being held, as that is stored in the levels of synaptic facilitation. This results in a memory network that is robust to noise and is able to maintain multiple items

concurrently. The above features are not straightforwardly reproduced within the attractor and the single-cell bistability frameworks.

Modeling studies have been instrumental in identifying physiological mechanisms that could underlie WM functions and more specifically active memory maintenance. These mechanisms are not exclusive. It is very likely that they all play a role in WM functions to allow the flexible maintenance and manipulation of information that is required for complex adaptive behavior.
